Indeed, in reviewing the whole subject of endocrinology, I feel that our actual knowledge of the functions of the ductless glands is almost as limited, as must have been the knowledge of the qualities of blood, before the invention of the microscope. We have, however, come to realize more and more the great importance those glands have and since we have succeeded in diagnosing a pathological function of this or that gland, we have made every effort to find some means to influence and balance those pathological functions. So far, we had practically only one method, namely, the use of organotherapeutic extracts given in the form of tablets by mouth or in the form of a solution by hypodermic injections. Only those who have worked long enough with these methods know what remarkable clinical success we have often been able to obtain, and, on the other hand, how deeply disappointed we often were being at the same time unable to explain the reason for our failures.

During the last few years, two other methods to influence endocrine functions have become known. First, surgery in the form of transplantation of glandular tissue and in the form of vasoligation, better known as the Steinach operation. Second, the use of the röntgen rays.

It is the latter method that I intend to discuss but not without apolozing to the röntgenologists, into whose field of work I am apparently intruding. However, as an endocrinologist, I have had so much occasion to appreciate the tremendous value of the x ray that I feel sufficiently encouraged to talk about it and recommend its use. On the other hand, I have no intention of entering upon the technical side, which I will naturally leave to the much better informed specialist.

I may, however, be permitted to touch briefly upon a theoretical question, which I have discussed personally a great deal on my recent European trip. It is the much discussed question of the stimulation dose. It is not for me to decide this question one way or the other, but its discussion is more acute in the endocrine application of x ray than in any other field of röntgenology. It is a fact that we are able to improve glandular function by x ray radiation. To inhibit and depress an overfunction is easily understood, if we use destructive doses. But how can we explain an increased glandular activity without assuming a direct stimulation?

Professor Holzknecht in Vienna and his school absolutely and radically deny the existence of an x ray dose that will stimulate function and act without destruction. "In the beginning is death," says Holzknecht. That means x rays always destroy; destroy little in small doses,—destroy much in larger doses. Only in very small doses they may be indifferent to the living cells. Holzknecht, however, does not deny that frequent increase of glandular functions follows their radiation. His explanation is that the gland in certain pathological conditions cannot discharge the hormone properly but accumulates it in their cells. X rays will now injure these cells so that they cannot longer hold the hormone and a rather sudden discharge with the accompanying clinical symptoms takes place.

The opposite view is taken by Manfred Fraenkel in Berlin, who possibly is the most prominent worker in this special field and was the first to call attention to the great value of *Reizbestrahlung* (stimulating radiation) in general. In his many writings, he has again and again emphasized his belief in direct stimulating influence of weak x ray radiation and with Catani of Zurich he speaks of a biopositive effect of x rays (that means a life aiding influence) compared to the destructive bionegative effect of prolonged exposures. Most röntgenologists, with whom I have discussed the matter, share Fraenkel's views on this point.

In a number of animal experiments and tests on human beings, he was able to show that organs and tissues, which in a physiologically normal state cannot be influenced by x rays, become more sensitive and actually can be influenced as soon as they are in a physiologically changed and abnormal condition.

This law, as Fraenkel directly calls it, naturally is of greatest importance when it comes to radiation of endocrine glands and also of connective tissues to which an internal secretion in all probability will have to be accredited. This latter point is of special importance in the treatment of cancer, as we will see later on.

A book by Manfred Fraenkel called *The Rejuvenation of Women* (with a contribution to the cancer problem) has just been published by Bircher in Berne and is receiving widest attention in Germany and Austria. This book mainly deals with x ray radiation of the female genital organs and in my discussion of x ray radiation of the various glands, I will begin with the ovaries.

The ovaries, as well as the testes, deserve a special place among the ductless glands, since both are so-called mixed glands, having an internal, as well as an external secretion. At least, I feel justified in referring to ovulation as well as to the production of spermatozoa, as an external secretion. It seems fairly well established that this external secretion is a function of a different group of cells within these glands than the internal secretion and since it has been shown that these two sets of cells are not equally sensitive to x ray radiation, the peculiar relation of ovaries and testes to x ray radiation is apparent.

*Read before the annual convention of the American Association for Medicophysical Research, Chicago, September 27, 1924.

The clinical changes following a strong x ray treatment of ovaries are too well known to deserve a lengthy discussion. An x ray dose that will remove a fibroid tumor of the uterus is usually more than a castration dose to the ovaries and is followed by all the corresponding clinical symptoms, similar to those following surgical castration; however similar only, not quite identical.

If the x ray dose was not large enough to destroy the entire ovary—the interstitial cells of the ovaries together with the follicular apparatus,—the complete symptoms of castration do not appear. Frequently an almost rejuvenating effect has been observed. Steinach and Holzknecht, as well as others, have described this fact and the Steinach method of rejuvenation for women is based on these observations. The explanation that Steinach offered is that the same x ray dose that destroys the follicular apparatus, causing sterility and amenorrhea, stimulates the interstitial tissue, or as he calls it, the female puberty gland,—thus producing an increased output of internal secretion. This view is shared, especially by Groedel, who has reported excellent results with ovarian radiations in climacteric complaints.

According to Fraenkel and my own observations, it is not necessary to use an x ray dose large enough to destroy the follicles in order to produce a stimulation of the inner secretory apparatus of the ovary. A much weaker dose, although repeated several times, has proved sufficient to balance a gonadal hypofunction. Besides Fraenkel, many others have used weak x ray radiation for the ovaries and have reported satisfactory results, for instance, Thaler in Vienna. He compared the result with the shaking up of a watch that had stopped and now resumed its normal work.

In a similar way, I think we should explain the effects of radiation on all glands, and as we should not differentiate too sharply between hypofunction and hyperfunction of a gland (unless pronounced) and rather speak about dysfunction, we should not separate too radically an inhibition from a stimulation dose. The same dose may in a given case inhibit and stimulate a gland at the same time, because each endocrine gland has a great number of functions, due to the polyvalency of their hormones. Besides, the same dose may inhibit glandular function in one patient and stimulate in another. The biological factor in x ray work is still too often neglected. Therefore, I would suggest that we designate those radiations which are not meant to destroy and definitely suppress function as regulating or balancing radiations, in differentiation from a "depressing or paralyzing" dose, whereby it is understood that such a regulating treatment may have in a given case a purely stimulating and in another a purely retarding effect. Our regulating x ray dose here would correspond to Fraenkel's biopositive radiation while the bionegative radiation would be a paralyzing dose. With this explanation and designation, we might be able to bridge over some of the differences between the adherents and the opponents of the stimulation dose theory.

The difficulty in treating the ductless gland by x ray naturally is to determine, first, which gland is to be exposed, and second, how strong or how frequent the exposure should be. I usually begin with a mild exposure, one tenth of an erythema dose or less and let individual response of the patient guide my further treatment. In order to exclude purely suggestive results, I frequently follow Holzknecht's practice in giving the first exposure as a pseudo-treatment, using a lead filter. As a rule, large doses are rarely necessary to regulate glandular function because they usually do not succeed where small or moderate doses have failed.

Let us now return to ovarian radiation. For the retardation of age, I, myself, have treated over one hundred patients showing signs of a congenital or acquired hypofunction of the ovaries. As you notice, I am not using the word rejuvenation because this word, as I have frequently stated before, leads too easily to exaggeration and therefore I prefer to speak about restoration or regeneration or, as Paul Kammerer calls his book on the subject, *Prolongation of Human Efficiency*. I have used from three to six x ray treatments, seven to ten days apart, never applying more but often much less than one quarter of the socalled castration dose at one time. I may be permitted to report briefly my own experiences here by giving you the conclusions only, as time will not permit going into details of case histories. A great majority of my patients were women around the menopause, some, however, as much as fifteen years after, their ages ranging from thirty-five to sixty-five. The principal complaints were those incident to the menopause and premature or beginning senility, declining physical and mental vitality, lack of endurance and power of concentration, constant fatigue, waning memory and general decrease of those faculties that were most vital to the individual in question. In over one hundred of my cases, I have not used the original Steinach method, consisting of x ray treatments alone, but in addition to the x ray treatments, I have given a series of fifteen to thirty diathermia treatments to the ovaries, one every day or every other day. This combined treatment suggested itself to me after I had learned from Steinach a year ago that he was then using diathermia for the purpose of regeneration.

This method found its way into the press a few weeks ago, but unfortunately in such a misleading manner that I feel it incumbent upon me to give at least a brief description of it today. Further details, as well as the fundamental animal experiments, will in due time be published by Steinach. Professor Steinach feels rather hard hit by some newspaper publicity given to him and his work, so much so that I welcome the opportunity to mention this fact here and since some misunderstanding has arisen about my personal relationship to him, (I have been called his sole representative, etc.) I am also anxious to state that this relationship consists in my being in frequent communication with him, in my practising his methods in accordance with his teachings and being in general an adherent to his theories. The cause of those misunderstandings probably lies in the fact that I was the first one to introduce his methods to the American profession and the first to publish corroborating evidence.

After this personal digression, let me return to the results, which I had with my combined x ray

and diathermia method, in which Dr. Wyser of the x ray department of the Mount Sinai Hospital, New York, has assisted me. The course of treatment usually took from four to six weeks, each diathermia treatment from fifteen to twenty-five minutes. Both ovaries were treated at the same time, the electrodes placed one above the symphysis or intra vaginam and the other on the sacrum. The idea naturally is that by producing a hyperemia in and around the ovaries, an increase of function will result. In applying x ray radiation immediately afterwards, a smaller dose is required to produce the desired effect on the heated and, therefore, more sensitive organ. The heated part of the skin is either protected and x rays applied from another direction, or the skin allowed to cool off sufficiently.

The result that I achieved in about one hundred cases is summarized in the following: In about seventy-five per cent. of my cases, a distinct improvement of glandular functions was accomplished. Objective evidence was a drop of blood pressure, often to a very marked extent, especially in cases of functional hypertension, an increased appetite and gain of weight in emaciated patients, a change of skin reaction toward developing the red thyroidal line, replacing a white adrenal reaction. In this change, I see an indication for better thyroid activity induced by improved ovarian function. This is quite parallel to the effects seen in men after vasoligation. The menstruation often received a marked alteration. In some cases, menses appeared again after many months' cessation, normal in character and continued regular, in one case already over a year. In other cases an irregular and abnormal menstruation assumed again the character of years ago. In some cases, however, the mild radiation of the ovaries did not succeed in checking the onset of the menopause or removing its troublesome symptoms. Here pituitary or thyroid radiation or both would be indicated according to the patient's endocrine constitution. Occasionally, I have distinctly observed a stimulated growth of hair and nails, both assuming a healthier appearance. The same was shown in the skin, in the form of a better complexion and tension. I purposely avoid the word youthful in order to forestall exaggerated ideas of a rejuvenated appearance. The lay mind is already connecting the Steinach treatment too much with the beauty parlor. It is not a beautifying but a reenergizing treatment.

Regarding the subjective symptoms, I want to be brief and not enumerate details, since autosuggestion cannot always be excluded. However, the majority of women who underwent the treatment asserted that it accomplished for them what they wanted and that they felt their constant and excessive fatigue gone and their vitality of former years returning. All my observations are similar to those of Fraenkel, as described in his book.

The length of time that the regeneration and restoration of efficiency can last is difficult to judge from only a few years' experience. A year ago, I reported my first six cases, treated with x ray alone (1). Three patients I have been unable to reexamine but the other three have remained in excellent health. One patient (Case I) was already sixty-four years of age at the beginning of the treatment. In one case (Case III) the patient received only one treatment, I had to repeat two x ray radiations with perfectly satisfactory result. The patient, now over fifty is doing a great deal of strenuous work, that she could not do before the treatment.

Some patients, naturally, have failed to respond sufficiently although they were benefited somewhat. Total failures I consider those where not the slightest objective symptom could be discovered to corroborate the subjective ones, even if they were mentioned by the patient. Those failures will probably have to be explained by lack of response from the ovaries themselves or from other glands to the ovarian stimulation and in those cases I have tried to influence other glands directly by x ray, chiefly thyroid, pituitary and adrenals.

Before discussing the indications for x ray treatment of other glands, I wish to summarize the indications for ovarian radiation and say a few words in regard to the testes. In clinics in Vienna and Berlin, where I had the opportunity to observe the methods in use, doses to inhibit function, the socalled sterilization dose is used in cases of hemorrhage and in benign tumors of the uterus, in cases of adnexal diseases, for the prevention of pregnancy and in cases of osteomalacia. Weaker doses for the purpose of balancing and stimulating function are used in cases of amenorrhea in younger women; then for the purpose of rejuvenation and regeneration in the sense of Steinach and to combat the distressing symptoms of the menopause. In the latter cases however, as we will see later on, pituitary radiation is gradually gaining preference. Fraenkel mentions remarkable results with his mild ovarian radiation, in certain cases of Graves's disease, in pathological obesity and epilepsy.

While the indication for ovarian x ray radiation is rather large, the treatment of the testes is not only quite limited but also rather unsatisfactory, as far as our present experiences go. I have used röntgen rays on the testes in cases of supposed hypofunction, administering at the utmost the sterilization dose in from three to five treatments. We can this way easily obtain temporary sterility but the clinical symptoms of an improved gonadal function were not very apparent. The effects of radiation cannot at all be compared with those following vasoligation.

A great deal more could be said about the effects of x ray on the male and female gonads, but it would lead too far and I would rather mention some of the work that is done in Germany and Austria in regard to other glands.

The discussion of the male gonad would not be complete without at least briefly mentioning the prostate gland. That prostatic hypertrophy, especially of the soft character, readily yields to the x ray radiation is well known. It is, however, still somewhat doubtful whether the large doses that are employed for this purpose directly destroy the prostatic tissue, or whether the scattered rays hitting the testes are also responsible for the result. The observations made after the Steinach operation in regard to the decrease of prostatic hypertrophy seem to support the latter theory. On the other hand, the doubtful results with testicular x ray radiation, speak against it. Philips, New York, for instance, has not seen any

favorable effects on the hypertrophied prostate by testes radiation alone.

Let us now come to the thyroid and pituitary glands. The thyroid was the first gland to be subjected to x rays. A great deal has been written about röntgen treatment of goitre and Graves's disease, so that I do not have to dwell on this indication, especially since large paralyzing doses are employed and we are more concerned here with the mild regulation doses. Such doses are recently being used for the thyroid, for reasons which will be rather new to many of you. I have, for instance, found mild thyroid treatments very valuable in addition to weak ovary radiation in cases of premature and physiological senility, amenorrhea and climacteric complaints. I fully agree with Fraenkel's and Leschke's opinion that mild radiations of thyroid, pituitary and adrenal glands, in addition to the ovaries, will play an important part in the problem of rejuvenation. I personally have employed these combined radiations already in several cases, as mentioned before, and have the distinct impression that they offer greater possibilities than when ovarian treatment is employed alone.

I also repeat that the difficult part is to decide in the individual cases which gland or glands should be radiated, where we should try to inhibit function by proper doses, and where only the regulating and more stimulating effect is desired. Only a careful study of the patient's endocrine makeup and deficiencies can give us the necessary information.

Let us return to the thyroid alone. Holzknecht and his assistant Borak in Vienna, have told me of a highly interesting series of treatments, which since they are now being published, I am probably allowed to report at this time. They have treated thirty patients, whose chief symptom was the great distress of blushing. Fifteen of these patients were treated with thyroid radiation and twelve of them were decidedly improved or cured. The other fifteen were treated with pituitary radiation and only two have shown an improvement. Thinking of the great vasomotoric influence of the thyroid, we can very well understand these results, either assuming that an inhibitory effect or an impetus to better balanced function has been given by a regulating dose.

While pituitary treatment has decidedly failed in these cases, a large field of indications for pituitary radiation has been opened by the recent work of Viennese clinicians and röntgenologists, of whom I will only name Holzknecht, Borak and Werner. Of those who have called attention to the possibilities of pituitary radiations before them I should mention Fraenkel, Hofbauer, Sahler and Stettner.

A few words about the technic. A small field about two square centimetres on each temple is exposed and in the average one quarter to one half of an erythema dose is applied. Kriser, Vienna, has devised an ingenious instrument, which is attached to the patient's head in such a way that through a kind of pointer, any number of places are indicated anywhere on the patient's skull, where x rays would always hit the pituitary. For weak radiation, the instrument is possibly too complicated, especially since the two fields easily to be indicated over the temples are sufficient. For the frequent treatments of pituitary tumors, however, Kriser's apparatus is of great value.

The indications for pituitary radiation are manifold. Borak in Vienna has just published a very excellent article on The Therapeutic Successes through Röntgen Radiation of the Hypophysis. He considers a number of indications for pituitary radiation already so well founded that they deserve fullest attention from the medical profession. We need not discuss the treatment of acromegaly since the main purpose of x ray treatment in this disease is the destruction of a tumor. The most frequent indications for regulating radiations of the pituitary are the following: amenorrhea in younger women, especially those cases where mild ovarian radiations have failed, dysmenorrhea and the complaints of the menopause, such as flushes, sudden perspiration, attacks of dizziness, headaches, pruritus vulvæ, etc. Promising observations have further been made in the treatment of certain cases of diabetes, pathological conditions associated or caused by a hyperfunction of the pituitary are more amenable to treatment than those due to a hypofunction. He radiates the pituitary from one to four fields, that means from both temples and from the forehead using about one third of an erythema dose from each field.

Next to the pituitary, the adrenal glands have to be considered but unfortunately very little is known as to their reaction to x rays. Zimmern and Cotenot have seen a decrease of high blood pressure which, however, could not be verified by Groedel. Drasel has seen a decrease of blood sugar in diabetes but positive confirmation likewise is lacking. I myself have seen an occasional tonic effect from very mild exposures and would suggest trying them in cases of asthenia. I am, however, not in a position as yet, to give any definite indications for adrenal radiations.

More and better founded are the indications for radiation of the spleen. With much larger doses than usually applied to endocrine glands, an increase of function has been observed. Stephan succeeded in increasing the coagulability of the blood to a marked extent. Corroborating evidence was furnished by Fraenkel and Werner, who could control hemorrhages in normal persons, as well as in hemophiliacs. A whole erythema dose and more was applied in order to produce this functional increase. Here is an example of how relative the conception is of stimulating and an inhibiting dose.

Closely related to the spleen is the liver. A checking of hemorrhages seems to be possible through liver radiations also and x ray exposures of either gland have shown to produce a marked increase of urea output.

I come now to the discussion of the last gland, the thymus, which will give me an opportunity to also touch upon the new and daring views of Manfred Fraenkel in regard to cancer.

The radiation of the thymus has become rather well known in connection with the treatment of psoriasis. Klingmueller, Bruck and others have described good results, assuming an increase of thymus secretion following radiation. Others again have denied any influence. Thymus radiation has also been described as successful in certain cases of Basedow's disease and Fraenkel believes that mild

thymus radiation, together with radiations of other endocrine glands, have a strong influence on the growth of connective tissue. In this he sees the protection against the invading cancer cells, at the same time attributing to connective tissue the functions of a gland with an internal secretion. He is convinced that x ray exposures of cancerous tissues decidedly too weak to destroy anything, can actually bring about a cure of the cancer and he proposes as a new method of cancer treatment by x ray, to use mild doses on the cancer itself with the intention of strengthening the surrounding connective tissue instead of injuring it by destructive doses. He would rather leave it to the stimulated and strengthened connective tissue to fight against the cancer than to the direct influence of enormous x ray applications. The mild radiations of other endocrine glands, especially those that show signs of weakness in the individual case, he likewise recommends and this is the way he concludes his aforementioned ingenious little book on *Rejuvenation of Women and the Cancer Problem.* He says:

"We must not be satisfied to assist the organism in which a cancer already exists by increasing the function of the ductless glands and thus combat cachexia, but we must already begin to use function improving x ray doses in cancer suspects, for instance, members of socalled cancer families. In these people, we must pay careful attention to early symptoms of age and must try to accomplish a rejuvenation in the sense of Steinach by systematic radiation with biopositive doses. In the huge surface of the skin, in the numerous glands with an internal secretion that are distributed everywhere, working harmoniously in wonderful relationship to each other, nature has presented us with an extraordinary gift, whose importance we only now begin to grasp. To utilize wisely this gift according to the laws of nature by applying x rays in an appropriate way must be our next goal in combating and furthermore in the prevention of cancer."

For this very new and rather sensational idea, Fraenkel lays claim to sufficient clinical justification, which he has drawn from the observation of six thousand cases. The linking of rejuvenation with the cancer problem itself, is not new. A great benefit for cancer cases has justly been maintained for the Steinach operation but the idea of cancer prevention instead of cure, almost comparable to vaccination, by systematic rejuvenation treatments is quite startling in its conception. I can personally say nothing as to the practicability but I am satisfied to say that a regeneration and restoration of the vitality of younger years is actually possible for the aging organism,—the most practical method in my opinion being the Steinach operation in men and systematic regulating x ray radiation of the endocrines in women.

The Effect of Ultraviolet Light on Blood Chemistry

DONALD McCASKEY, M.D.

New York

An amazing mass of clinical data have accumulated within the past decade regarding the therapeutic benefits from quartz or ultraviolet light. Those of us who have been working with this agent have observed very significant and absolute surefire results accrue in a patient's tissue metabolism. We don't know yet how the effect is produced in elaborate detail. But we do know that in many instances quartz light is a specific and also an absolute life saver.

It will be of scientific interest, therefore, to study the comparative blood chemical findings on a male patient after six consecutive years of quartz light therapy, from the age of thirty-eight to forty-four. Likewise to observe the result comparatively after two subsequent years, from the age of forty-four to forty-six when no ultralight therapy was administered.

June 9, 1916. Blood taken by Dr. William G. Lyle, Harriman Foundation Research Laboratory, Roosevelt Hospital. Patient a male, aged thirty-eight years.

On August 28, 1922, six years later, the patient then aged forty-four, I had Dr. Oliver S. Hillman make a complete blood chemical analysis. Note the six year comparisons:

1916	1916	1922
Blood pressure	125 (systolic)	120
Hemoglobin	88 per cent.	96
Differential count		
Polymorph	42 per cent.	64
Lymphocytes (small)	50 per cent.	30 per cent.
Lymphocytes (large)	1	2
Eosinophiles	5	4
Basophiles	1	0
Red blood cells	No count made	5,110,000
Whites	" " "	7,000
Total nonprotein nitrogen.	29.4 mgm. per 100 c.c.	34.6
Urea	28.5	23.9
Creatinine	0.57	1.1
Uric acid	2	3.2
Sugar	106	100.0
Carbon dioxide	47 per cent.	66.2 per cent.
Chlorides	not taken	473
Urea nitrogen	" "	11.2

In the beginning of treatment of this patient, the dose from an alpine sun ultraviolet lamp started at one hour a week, twelve inches from the burner, the naked body being exposed and its areas shifted every few minutes. After six months two burners were used. Patient's general improvement became quite apparent, both in physical endurance, in relief from insomnia, in digestive ability and in sexual power.

During the second year the dose was increased to two hours a week, the burner being eight inches from the naked body.

During the third, fourth, fifth and sixth year, the patient became more adept, and the dose was increased up to four and occasionally five hours a week. Often the burner would be placed six inches and frequently four inches away, when the heat could be endured. Patient's skin became deeply tanned, and his physical and mental condition reached an ideal state both subjectively and objectively.

As will be observed from the 1922 blood chemical analysis, the significant signal organic benefit in the blood stream was in the jump of oxidizing power of the carbon dioxide—a jump of twenty per cent.

Between the years 1922 and 1924, patient discontinued treatment, not even enjoying the sun's rays at the seashore. His diet was much reduced, and on July 24, 1924, at the age of forty-six, the patient presented himself for another blood analysis. I had Dr. Oliver S. Hillman again take a complete blood chemical checkup. It registered

Blood pressure 118-76; hemoglobin	90 per cent.
Red cells	4,700,000
White cells	4,200
Color index	.95
Polymorphonuclears	39 per cent.
Small lymphocytes	56 per cent.
Large lymphocytes	5 per cent.
Eosinophiles	0
Basophiles	0
Nonprotein nitrogen	42.5 mgm. per 100 c.c.
Urea nitrogen	17.3
Urea	37.0
Uric acid	4.2
Creatinine	3.2
Sugar	147.0
Chlorides	487.0
Carbon dioxide	66.2

The comparative study of these findings after a two year period without any ultraviolet light reveals a drop in hemoglobin, red blood corpuscles, white corpuscles, a drop in the polymorphonuclears, and a marked rise in blood sugar, nonprotein nitrogen, uric acid and creatinine. It is interesting to observe that the carbon dioxide combining power with the blood plasma remains unchanged, and still stands at sixty-six per cent., whereas eight years before it stood at forty-seven per cent., from which point it was built up, and at which level it is still holding.

The condition of the patient clinically is not that of a marked virility such as he possessed two years ago when he terminated his quartz light therapy. He does not have the degree of endurance he possessed. His insomnia has returned. His digestive mechanism is not running smoothly, and he states furthermore than his sexual power is likewise greatly lowered contrasted with the period of uviol radiations.

In conclusion, therefore, while we do not yet know how quartz light produces its blood chemical and clinical changes, the above six year record with large doses of quartz light constitutionally upon the naked body consistently carried out, and the contrasting two year period without any uviol radiations whatsoever, show very conclusively that such physiological changes as are produced from quartz therapy are eminently constructive, and belong to the plus side of the patient's vitality ledger.

There is no case reported in all the literature which covers with blood chemical analyses a period of six years with a subsequent lapse of two years, and it will be interesting to make further observations and analyses along this line. Someone has described quartz light as an ultraviolet vitamine. For want of a better term, it is certainly a fitting one.

Closure of Bronchial Fistula of Twelve Years' Standing by Use of Radium

WILLIAM L. HARRIS, M.D.
Providence, R. I.

The nonsurgical treatment of a bronchial fistula has always been a troublesome task. Following the rupture of a pulmonary abscess into the pleural cavity the opening into the bronchus may close some weeks after the resulting empyema has been drained, but this satisfactory result is by no means a constant one. Usually, after months of surgical care have failed to bring about the closure of a bronchial fistula, the sufferer, on account of distressing symptoms, will submit to further surgical intervention with results that are not always satisfactory, as permanent closure of a divided bronchus is not always possible. Furthermore, since the operation is one of very considerable gravity, any other method offering possibilities of success may well be worth considering.

The characteristic, extensive fibrosis which follows the application of radium to vascular tissue (as in the treatment of an angioma), suggested the use of radium in the following case of long standing bronchial fistula:

Case.—Patient, male, forty-five years old, weighing 270 pounds, had an empyema following an attack of pneumonia. Under local anesthesia, a portion of a rib was resected and the pleural cavity drained. At the end of one year there was no improvement in patient's condition, and, as at the age of seventeen (?) he had been operated upon for suppurative cervical adenitis, the continuation of the discharge with the persistence of the bronchial fistula suggested the possibility of a tuberculous process. During a period of more than twelve years drainage ceased several times. Upon one occasion the patient seemed perfectly well for about eighteen months. During these years it was necessary to reopen the pleural cavity many times, and upon each occasion the opening into the bronchus was always in evidence.

For the greater part of this long period the discharge was so profuse that dressing twice a day was necessary. Infection of the skin covering the chest caused much distress and for some years daily treatments of the entire chest wall with the quartz light was the only means of securing relief. Upon several occasions the long sinus seemed about to close, but this desideratum always represented a false hope, and the necessary reopening and extensive dissection of the fibrous pyogenic membrane running through a greatly thickened pleura was always followed by the whistling gurgle through the bronchial fistula.

As a forlorn hope the use of radium was suggested, the idea being entertained that the tough fibrous membrane would disappear, and that deep introduction of the radium element might produce a fibrosis, with subsequent contraction of the vascular pulmonary tissue in the neighborhood of the patulous bronchus bringing about its closure. Within a period of ten weeks about 4200 milligram hours of radium treatment were given, directed at different portions of the sinus, and within four months the thickened scar tissue had disappeared. The sinus, which measured about seven inches, gradually closed and for the past eighteen months the patient has been perfectly well. I can not but feel that the patulous bronchus was responsible for the many years of drainage from the pleural cavity and that, following the destruction by radium of the endothelial cells lining innumerable capillaries in the pulmonary tissue surrounding the ruptured bronchus (thus transforming the capillaries into fibrils—which automatically contract), the opening into the bronchus was occluded. To have attempted its closure by surgical intervention in this patient weighing 270 pounds would have been most hazardous, and indeed it was never considered.

I have so often seen satisfactory results following the use of radium in conditions where fibrous indurations, by interfering with drainage, were impeding recovery, that I feel in this element we have a most potent agent to aid us when confronted by abnormal areas of fibrous tissue.

Hydrophobia and Carriers

H. RAHMET BEY, M.D.
Cairo, Egypt

The main theme of this article is carriers in rabies; but it is essential to give a synopsis of the disease beforehand. Hydrophobia (rabies canina or lyssa) is a Greek derivative meaning the dread or fear of water. It is a disease of dogs and other animals and is invariably transmitted to man by the bite of a rabid animal. Delauny, Gohier, Fernel, Schenkins, Sanzoni, and Alfadi, believe that the disease is transmissible by the alimentary tract; Decroix, however, is opposed to this view, and to prove it he ingested the saliva of a mad dog without contracting the disease. It is very likely that the digestive juice destroys the virus; but this would only be true if the walls of the alimentary canal were intact and the digestive juices normal; otherwise there is a possibility of the ingress of the virus.

The disease is infectious and might be transferred even in the incubation stage, i.e., before the symptoms have set in. Not every person bitten by a rabid animal develops hydrophobia. This fact might be accounted for in one of three ways, viz, the saliva of the biting animal might be wiped off the fangs while penetrating the clothes of the bitten person; the inoculated virus or its dose might be weak, or the person bitten might have an acquired or inherent immunity. Rabies can be produced otherwise than by the saliva from a bite, namely, by inoculating with the fluids and tissues, especially the brain and cord of a rabid animal.

ETIOLOGY

Hydrophobia is an inoculable and transmissible disease. It therefore must be due to some germ which so far has not been definitely identified. Pasteur found round and refractive bodies in the central nervous tissues. Fol was able to isolate and cultivate round granules from the marrow of infected animals. Babes produced rabies by inoculating with a microbic culture obtained from the nervous substance of rabid animals. Bruschettini found a bacillus and Memuro a blastomyocyte, as causative factors of the disease. Negri and Guarniere ascribed it to protozoa. Negri in 1903 found the bodies, called by his name, in the nerve cells of animals dead with lyssa. They are oval or round and consist of protoplasmic masses containing inner bodies. They likewise have what resemble spores. These bodies are abundantly found in the street virus but with difficulty in the fixed one. In the stage of excitement the Negri bodies are found in numbers. They become smaller in size and ultramicroscopic with the abatement of the virus, especially about the seventh day. Negri considered these bodies to be protozoic in nature.

Babes, however, showed that they were end results of the rabic infection rather than the factors causing it. Proescher demonstrated numerous spirochetes, cocci and bacilli as the cause of the disease.

In 1903 Remlinger demonstrated that the filtrate from a Berkefeld filter of brain matter of infected animals, contained the infection; he thus proved that the disease was due to a filtrable virus. Noguchi in the same year discovered pleomorphic, chromatic bodies which colored well with the Giemsa method; they are filtrable, invisible and according to him play the principal pathological rôle in the production of the disease. Puntoni and Bouffard believe in the plurality of the virus of hydrophobia.

The virus of rabies in rapidly destroyed by a temperature of 90° C. (Roux); it is likewise de-

stroyed within twenty-four hours at a temperature of 45° C. Cold conserves the virus; Gibier kept the cadaver of a rabbit dead with rabies for ten months at a temperature of 10° C.; at the end of this period the virus was still virulent. Drying or desiccation rapidly destroys the power of resistance in the germ of this disease.

The microbe of hydrophobia is found in the saliva or salvo of the infected animal; Gruner and Count Salm proved this in 1813; this was later confirmed by Magendie and Breschet, who inoculated two dogs with buccal saliva of a rabid man; one of the dogs developed the disease. Hertwig showed the virulence of the saliva from the parotid gland.

The virus may likewise be found in the lacrymal and mammary glands, bronchial mucous membrane, pancreas, and the suprarenal capsule of infected persons; some maintain that the milk of the victim contains the virus. The blood, lymph, lymphatic glands, liver, spleen and urine, are free from the germ.

Nocara and Roux proved the virulence of the saliva of infected cases, three days before the development of the disease, i.e., before the symptoms set in.

PATHOLOGY

Once infection has taken place, the virus attacks the nervous system. Pasteur, Galtier, Cumberland and Roux have proved this. Inoculation with brain fragments, bulb, spinal cord, and cerebrospinal fluid, is certainly followed by rabies. Portions from the bulb are the most virulent of all. Inoculation from the bulb under the dura is followed by the disease in twelve to fifteen days. The virus travels exclusively along the nerve paths. Experiments by different authorities have shown that the poison principally affects the spinal cord and destroys its nerve cells. The virus may be lodged in the peripheral nerves but this is not constant.

On the whole there are no gross pathological findings; but there are hyperemia and moderate edema of the brain, spinal cord and their membranes. The throat region with the lymphatic glands around and the mucosa of the digestive tract are usually congested; the lungs and kidneys present a general congestive condition. The whole picture shows the presence of an intense irritant in the circulation. The blood is dark; there might be minute hemorrhages and clusters of lymph cells about the blood vessels. The Negri bodies are found in the brain.

SYMPTOMS IN DOGS

Since rabies is primarily a disease of dogs, it is worth while to glance at its course in these animals. Hydrophobia in dogs manifests itself in two forms, the raving and quiet. In the raving variety, there are three stages. In the first stage of prodromata, there is melancholy, which lasts from one to three days; the animal is timorous and has no appetite. The second stage is the irritative or manic state; here the animal is prone to bite and has a peculiar, low howl; it roves about and runs away from habitation; its appetite is perverted and it swallows straw, wood, hair, earth, stones, etc. The third stage is the one where paralysis supervenes; the dog looks lean and wretched. The paralysis is specially pronounced in the hind legs which drag along and in the lower jaw which falls and from which the saliva dribbles. The animal dies on the tenth day from the onset of the disease, at the latest.

The quiet form is similar to the raving in the prodromal and paralytic stages, i.e., it runs its course without the second or irritative stage.

SYMPTOMS IN MAN

The disease has a period of incubation and three stages. The incubation period varies from three to six weeks, but this is not constant, for cases of ten days' duration and others of over a year, have been reported. In the young incubation is generally shorter than in elderly persons. During this period the infected person feels perfectly normal.

First or premonitory stage.—Shortly before the onset of the disease and extending from one to three days some ill defined symptoms; such as indisposition, malaise and anorexia, manifest themselves. There is uneasiness and the sense of dread as if evil was impending. Pain, tenderness, and congestion of the cicatrix of the bite with swollen lymphatics in the neighborhood, manifest themselves. Headache, mental depression, irritability, sleeplessness, great anxiety, and aimless wandering sooner or later declare themselves. Even in this prodromal stage, marked aversion to liquids may be manifest. Hyperesthesia, such as sensitiveness to light and currents of air, soon sets in. The full development of this stage is ushered in by a spasm in deglutition; there is a sense of choking and tightness about the pharynx, with difficulty in speaking and swallowing. The dread of fluids, though there is intense thirst, is due to this condition. The pharyngeal mucous membrane is congested; as a result of this there is an abundant secretion of saliva which is hawked and spat because it could not be swallowed. Oppressive breathing with suffocation may supervene. This stage may last a day or two.

Second stage.—This is the stage of excitement; it is marked by peculiar and characteristic tonic convulsions. The spasm in the muscles of deglutition and respiration becomes tenser and swallowing becomes impossible. The mere suggestion of swallowing may cause a spasm; the slightest agitation or touch suffices to provoke a convulsion; a sensation of impending suffocation is felt. The whole muscular system may participate in these spasms; these convulsions are separated by periods of complete relaxation.

Generally the mental faculties remain unimpaired, though there might be mental terror. Hallucinations occur at intervals and may run into mania. These paroxysms may last from twenty-five to fifty minutes; during these paroxysms dyspnea, restlessness, and excitability dominate the scene. In rare instances food could be swallowed though with great difficulty. This stage may last from thirty to seventy hours. Death may occur here amidst the convulsions from exhaustion and asphyxia.

Third stage.—This is the stage of paralysis; it is brief and may last from two to twenty hours. There is a gradual remission of the severe symptoms; general debility and prostration rapidly increase. The nervous excitability becomes less when respiration becomes freer and when the ability to swallow is

partially recovered; the convulsions become feebler and soon disappear. A condition of rapidly ascending paralysis generally supervenes; symptoms of cardiac and respiratory failure declare themselves. This picture terminates in death.

At the commencement of the disease the pulse is normal but soon begins to grow weaker and more rapid as the disease progresses. There is a rise in the bodily temperature and scanty traces of sugar.

This chronology of symptoms does not necessarily take place in every case, as some symptoms might be exaggerated and others overshadowed.

DIAGNOSIS

Once the symptoms have set in the picture becomes unmistakable, especially when the history of a bite is traced to a rabid animal. The conditions that might be mistaken for hydrophobia are hysterical hydrophobia (hydrophobia imaginaria lyssophobia) and tetanus; rarely lethargic encephalitis. The virus of the latter and rabies leave the system by the saliva as shown by Strauss, Hirschfeld, and Loewe. However, a careful study of the case will eliminate all doubts.

PROGNOSIS

This is generally fatal once the disease has declared itself; but there are a few patients who have recovered.

TREATMENT

The treatment of rabies is purely preventative. No curative medicine has been discovered so far; some maintain that salvarsan is curative in rare instances; however, this has not been proved. Once the disease has set in, the treatment becomes merely palliative. The preventive treatment resolves itself into the local and systemic. The former consists of thorough disinfection, cauterization, and even excision if the patient is seen early enough before absorption has commenced. The systemic treatment was inaugurated by Pasteur, which is done by vaccination with the attenuated virus. A retrospective glance at Pasteur's method might not be out of place.

Pasteur had observed that a few of the dogs experimented upon with rabies became refractory to new infection; from this he conceived the idea of procuring a virus that would not kill the dog but would confer immunity.

He had also noticed that if monkeys were inoculated from dogs, the period of incubation grew longer; again he noticed that if rabbits were inoculated from these monkeys, the incubation period grew less and less until it became fixed at the sixth or seventh day. He proceeded to inoculate with the virus of the minimum strength and progressively inoculated with more virulent material. By this process he was able to procure immunity against the active virus of maximum virulence. In 1884 he made a communication to the Institute on the subject. In 1885, in conjunction with Roux and Cumberland, he announced that they had obtained an attenuated virus by desiccating the spinal cords of rabbits that had died as the result of the inoculation with fixed virus.

Their technic was as follows: The spinal cord of a rabbit dead from rabies, was suspended in a bottle at the bottom of which fragments of caustic potash were placed, and the opening of which was plugged with wadding. Each day of suspension (a drying process) reduced the virulence of the infected cord until on the thirteenth or fourteenth day, the cord lost all its virulence. In immunizing the rabbits experimented with, on the first day they were inoculated with a portion of the cord that had been desiccated for fourteen days; on the second day they were inoculated with a portion of the cord dried for thirteen days; on the third day they inoculated with a portion twelve days old. They continued this process until the animals acquired absolute immunity. Joseph Meister who had been badly bitten by a rabid dog, was the first human being on whom the remedy was tried. He escaped getting the disease. The original course of treatment was ten days only; but it was found that this was insufficient in grave cases. A more intensive course extending from fifteen to twenty-two days was adopted.

The virus of lyssa is of two varieties, namely the street and fixed. The former is found in the animals infected with the natural disease. The virulence of this virus varies and when injected subdurally in rabbits it produces rabies at a variable period of time which ranges from fourteen days and upward. The fixed virus is produced by its passage through a long series of rabbits; in this way the virulence is increased for these animals when they ultimately take the disease after a certain fixed period of incubation. This virus is produced as follows: The bulb of a rabid rabbit is injected into another under the dura. The inoculated rabbit develops the disease in from twelve to fifteen days. As this process is repeated again and again, the incubation period is gradually reduced until it becomes fixed, or stationary on the sixth or seventh day. The incubation period cannot be reduced beyond this period. This crop of virus is called the fixed virus. The ways of inoculation are various. Trephining and introducing the virus under the dura is the modus operandi. Inoculation through the anterior chamber of the eye, is feasible. Inoculation can likewise be effected by injecting the virus subcutaneously. Here the results are less certain. According to Hermann the adipose tissue is not favorable to the absorption of the virus. Fat animals inoculated subcutaneously are less prone to develop rabies than lean ones. The intramuscular inoculation is more effective and certain than the subcutaneous. Persons bitten by rabid animals, are today treated with serum according to Pasteur's method, or with the serum-vaccine treatment.

SERUM TREATMENT

Marie and Remlinger have prepared a serum from vaccinated animals, which neutralizes in vitro the virus of hydrophobia. However, the curative and prophylactic effects of this serum have not given the desired results.

PASTEUR'S TREATMENT

This is done by inoculating with an attenuated vaccine. The virus is prepared by daily injecting rabbits subdurally with the fixed virus. At the death of these rabbits, the spinal cord is removed with aseptic precautions, cut into three parts, and suspended in a bottle plugged with cotton and having caustic potash in the bottom. The cords are kept in

a dark room at a constant temperature of 23° C. Thus a whole series of cords from one to fourteen days old are obtained, giving the various attenuations of the virus from pure virulence to nullity. The bitten person is treated in an antirabic institute where he undergoes the course of inoculations; the injections are usually done intramuscularly in the abdominal wall. The usual dose is a portion of the cord two to three m. m. in length. This is prepared for injection by filtration and suspension in normal saline solution or bouillon; it is in the form of an emulsion.

Downy and Couret advocate the use of the desiccated virus as superior to the classical method of Pasteur. They maintain that the immunity conferred by their method was earlier and greater than that conferred by the Pasteur method; the average length of treatment was from seven to nine days with them.

THE SERUM-VACCINE TREATMENT

In this treatment the vaccine and serum are combined. The mixture of two c. c. of the vaccine emulsion and four c. c. of the serum, is injected into the bitten person. This treatment is repeated for the four consecutive days; from the sixth day on, the vaccine emulsion from the desiccated spine, is used alone. The advocates of this method maintain that it confers immunity in a shorter time than that of Pasteur which requires fifteen days to confer immunity. Remlinger showed that the injection of sixty c. c. of the serum-vaccine into the eye of a sheep three days before the development of the disease, could prevent it.

CARRIERS

The generally recognized rule adopted toward the animal inflicting the bite and the person bitten, may be summed up in the following succinct statement. If the biting animal be caught alive, it is sent to an infirmary for animals where it is observed for about a week by a veterinary surgeon. If at the end of this period the animal shows no symptoms of rabies, it is discharged and the antirabies institute informed of the fact. If, however, the animal develops the disease, the brain and spinal cord are removed and sent to the antirabies institute where inoculations are made from the same and where the Negri bodies are looked for. If the biting animal be found dead, whether from disease or from being killed, its cadaver is sent to an animals' infirmary where the brain and spinal cord are removed and sent to an antirabies institute where they are examined as aforementioned. The bitten person is immediately sent to an antirabies institute to undergo the course of inoculations in case the biting animal is not caught or in case the bite is grave or about the head, face, or neck. If the biting animal has been caught and the bite is not grave and is in distal parts, the course of inoculations may be postponed until the result of the animal's observation is known. In case the findings are negative, whether as the result of the veterinarian's observation or the laboratory examination, the course of inoculations may be discontinued; in case the findings are positive, the course of treatment is carried on.

From the foregoing it is seen that medical authorities presume that every biting animal harboring the virus in its saliva must develop the disease within a week after the bite, that it must die from rabies, and that there are no carriers in this disease.

In medicine the word carrier means a person who harbors the germs of a particular infection without himself manifesting any symptoms of the disease produced by the said germs.

It can be stated in a general way that all infectious diseases have their carriers in one guise or another; hydrophobia is an infectious disease; has it carriers like the other infectious diseases? By deductive analogy one is bound to conclude that it has.

Case.—A boy, F. M., of Italian parentage, aged seven years, died of rabies in one of the hospitals on the twentieth of last September. The corpse had all the external signs of death due to some systemic irritant. On the anterior aspect of the middle of the right shin, there was a cicatrix of a bite wound with signs of recent reaction and congestion. A few days previous to death, the boy was seen by several doctors who all made the diagnosis of rabies. On the nineteenth of the said month he was taken to the hospital, where he died on the twentieth, the hospital confirming the diagnosis of the other doctors.

The father, who is an intelligent man, gives the following history and here lies the interesting point. He said that his son had been bitten by a dog about fifty-one days previously, i. e., about the thirty-first of last July; the boy was taken to the antirabies institute in Cairo, which is a thorough, efficient, and up to date one. Unfortunately, the father ceased to send his son to the said institute, because he saw that the dog was all right and showed no signs of rabies. After twenty-three days from the biting, he again saw the dog, which was in a normal state with no signs of madness; content with this false state of security, he failed to report to the police for action against the dog and sent his son and his daughter to Alexandria (a beach and summer resort of Egypt). On the sixteenth of September the boy asked for a drink and had an attack of revulsion when it was offered him. From then till his death he went through the several stages of hydrophobia.

Attempts without avail have been made since to find the dog. Now if the father's history is true, and there are no reasons to doubt his veracity, the dog that bit his son must have been a carrier, for he had seen it thirty-three days later and it was sound and normal.

Carriers are either convalescents or contacts; the latter term is used here in the widest sense including all sources of infection. Pouder in examining one hundred workers in a town with forty thousand inhabitants, that had been free for seven months from cerebrospinal fever, found thirty-eight per cent. to be carriers of the meningococcus. This shows how long a convalescent or contact may harbor the microbe.

Carriers do not manifest the disease because of their immunity to it. At the start it has been stated that the great majority but not all persons bitten by rabid animals manifest the disease. Persons who acquire immunity go through the fight, so to speak, between the invading germs and the natural defenses of the host; during this struggle the invading germs

exist in the said host; this contention is applicable to other animals than man. Now if a dog is going through such a state, its saliva will likely contain the virus of rabies and consequently is a carrier. If a person is bitten by it, the disease would likely develop in that person. This category includes all contacts.

Recovery from actual rabies has been attested for by Chantemesse, Savern, Roux, Sebell, Veresco, Courmont, and Lesieur; their conclusion is that only ninety-nine and a fraction per cent. of those who acquire the disease succumb to it, i. e., a fraction of one per cent. recover. This means that a dog or other animal may get the disease and recover from it. It is very likely that a man or dog in the convalescent state, harbors the virus of lyssa; hence an animal in that condition is a carrier and may infect others. The United States Public Health Report for 1912, by Stimson, stated that the mortality among those bitten by rabid animals and treated by the attenuated vaccine, is less than eight tenths of one per cent. According to Dr. Viala (1) the mortality among 33,388 persons treated for rabies, was only 0.38 per cent.; according to the last authority 395 persons were treated in the same Institute in 1912 with no mortality.

CONCLUSION

1. From the given facts it is evidently clear that there are carriers of rabies. Hence every biting animal should submit to a longer period of observation that a week; six weeks, the period of maximum incubation, would be better.

2. The biting animal should not be observed only by a veterinarian, but inoculations from its saliva (the medium of the virus of hydrophobia) should be continuously made as long as it is under observation.

3. Since the prophylactic treatment of lyssa is almost one hundred per cent. prevention of the disease's development, every person bitten by a dog should undergo the complete course of treatment.

4. All dogs in the streets and public places should be muzzled.

Decholesterinization

ARTHUR N. TASKER, M.D.

Washington, D. C.

Major, Medical Corps, U. S. Army

The concept of cholesteremia is of comparatively recent origin. It may be said to have been led up to by the investigation of calculi, not only in cholelithiasis, but in certain other conditions wherein the precipitation of cholesterin with the consequent formation of concretions is the fundamental characteristic. It seems generally accepted now that the primary cause of this morbid process lies in some disorder of hepatic function, the liver being apparently the regulating agent in the metabolism of cholesterin.

Cholesterin is a lipoid which does not contain phosphorus. It is found normally in certain tissues such as the brain, in the fluid of hydrarthrosis, in the contents of ovarian and mesenteric cysts, and to a certain degree in the blood. It may be said here that cholesterin is not, however, the only blood lipoid, for there are others of which the phosphatides, cerebrosides and lecithins are examples. In the normal human individual cholesterin is present in from 1.6 grams to 1.8 grams, while the total lipoids amount to 4.5 to 5 grams. Thus it is seen that cholesterin represents almost a third of the total lipoids.

The cholesterin content of the blood is dependent upon alimentation, since the administration of a diet rich in fat or in cholesterin will increase the lipoids and cholesterin in the blood even to the point of doubling them. In such cases the blood serum is frequently of a thin milky appearance, and this lactescence is one of the signs, though inconstant, of cholesteremia. But while the cholesterin of the body is in part of alimentary origin, it has also an endogenous source. The suprarenal glands produce it in considerable amounts, and during pregnancy the corpus luteum furnishes some. It is probable, furthermore, that the presence of this substance in other glands and tissues may mean a production therein in excessive quantities.

The cholesterin thus formed is dissolved in the blood and circulates therein in a state of colloidal equilibrium. It is increased not only as a result of eating brain tissue and eggs, but in certain physiological states as well (menstruation and pregnancy), and in certain diseased conditions such as arterial hypertension, diabetes, gout, and organic lesions like nephritis. It may be deposited in the connective tissue cells of the skin (xanthelasma), in the periarticular tissues, and in serous membranes. Chauffard and Troisier have shown conclusively the relationship existing between uric acid and cholesterin in gout. Cholesterin likewise is deposited in the eye forming the arcus senilis.

To relieve the body of its excess cholesterin there appear to exist in the blood and tissues ferments which oxidize and otherwise decompose a portion of it, but the larger part is eliminated through the liver, and it is found that the bile, of all animal fluids, is the one that contains the most cholesterin. Every increase in the blood cholesterin is reflected by an almost proportionate increase of this substance in the bile. If present in no more than normal amount it remains in solution or suspension, but when in greater concentration it shows a tendency to precipitate with the formation of calculi; and this tendency becomes more marked when the biliary salts are diminished in the presence of a cholecystitis, or when the gallbladder is invaded by a foreign body—no

matter how minute—which may serve as a centre of crystallization. We see here a tendency in pathological thought to substitute the socalled humoral theory of cholelithiasis for the previously held inflammatory and microbial theories. In general it seems to be true that biliary lithiasis depends in large measure upon the concentration of cholesterin in the bile, and this factor in turn depends upon the degree of cholesteremia present.

But this is not the whole problem. The mechanism of the elimination of cholesterin is fairly complex, and such elimination depends upon the proper functioning of the liver. The liver receives much more cholesterin than is eliminated in the bile, and the excess is metabolized (perhaps as a phase of the production of the biliary salts) by the liver. Hepatic insufficiency may, therefore, play a very considerable part in permitting an excess of cholesterin in the bile. Again, there must be considered the permeability of the biliary channels. Obstruction of these may bring about a retention of cholesterin in the blood, just as ureteral stenosis may result in an increase in the blood urea. From this it is easily understood why the blood shows an excess of cholesterin during an attack of jaundice. Hepatic insufficiency would seem then to be always the focal point of attack in the treatment of any disorder of cholesterin metabolism.

The therapeutic indications are three: To reduce the amount of cholesterin in the circulating blood, to overcome hepatic insufficiency, and to facilitate the elimination of cholesterin in the bile. In addition to dietary restrictions involving foodstuffs rich in cholesterin, other measures whose efficacy has been recently brought to light are interesting. The sugars, especially glucose and lactose, serve as active decholesterinizing agents. The rectal instillation of glucose in isotonic solution is the best method of administration. Ingestion by mouth is much less efficient, while subcutaneous injection secures very little benefit. Sodium benzoate and sodium salicylate given in daily doses of one gram over a period of four or five days will diminish the amount of cholesterin in the blood very measurably. Other salts of sodium may produce analogous effects. Uroformine, which exerts a tonic effect upon the gallbladder, may be combined with the sodium salts referred to. In connection with the physiology of the liver it is important to note that antipyrine definitely diminishes hepatic activity. Experimentally it has been shown that it lowers the amylase of the liver as well as interfering with the secretion of bile and the nitrogenous coefficient. In diabetes one gram of antipyrine has been observed to increase the bile cholesterin by approximately twenty-five per cent. The use of this drug should therefore be carefully controlled in individuals whose blood content of cholesterin is above normal.

So important is the whole question of cholesterin metabolism that it merits and will undoubtedly receive much more extensive and intensive study in the future than has been given it in the past.

Allergic High Blood Pressure and Its Control by Epinephrin*

I. S. KAHN, M.D.,
San Antonio, Texas.

Arterial hypotension to a rather marked degree seems to be the common finding in the severe chronic perennial asthmatic emphysematous bronchitis of many years' duration. Systolic readings of between 90 and 100 in the adult, are not at all unusual in cases of this type. However, an elevation of the usual blood pressure readings ordinarily accompanies the actual asthmatic paroxysm, falling again in the intervals between attacks.

Whether it is possible for an unusually high blood pressure to be instituted gradually and maintained by frequently recurring daily asthmatic attacks *per se*, —the hypertension thus becoming allergic in origin and character,—is a question difficult to answer, owing to the obvious nonexistence of known blood pressure findings anteceding the chronic asthmatic state. Also, whether it is possible for certain toxins of an antigenic character to produce coincidently immediate high blood pressure and asthma, is another question that can not be definitely replied to. The following cases, however, suggest the decided possibility that certain of these chronic high blood pressure cases accompanied by bronchitis or asthma may be totally or partially of allergic origin. The recognition of this fact is important, owing to the question that must at times arise, of the safety or advisability of the administration of epinephrin in cases of asthma presenting an elevated blood pressure, where the employment of this agent might apparently be considered positively contraindicated.

Naturally, in this connection, the myocardial dyspnea so frequently accompanying high blood pressure with beginning or advanced cardiac decompensation must be differentiated and ruled out,—and does not enter into this discussion.

The following cases exemplify the condition desired to be brought out.

CASE I.—Mrs. F. C., widow, aged fifty-seven, was first seen February 3, 1922. For several years she had suffered with winter bronchitis. Her first attack of asthma came on five years previously. The present attack of asthma started in Illinois in April, 1921, and had been almost continuous for ten months in spite of several changes in climate. She had been two or three weeks in San Antonio, desperately ill during the entire period. On admission to Santa Rosa Infirmary on February 1st, she had

*Read before American Allergy Association. Chicago, June 10, 1924.

been considered a probable wool feather animal hair type of asthma, and had been placed in a stripped room, and such contact absolutely eliminated. Similar attention was given to the eradication of all nonspecific mechanical irritants. Catharsis had been induced, and the patient had been too ill to take nourishment of any kind, thus eliminating etiological dietary factors.

The treatment the previous three days had consisted of epinephrin, twelve minims, with one eighth grain of morphine and one one hundred and fiftieth grain of atropine every four hours,—without the slightest benefit.

Examination revealed a woman in poor condition, suffering intensely from bronchial asthma with the usual chest findings typical of this condition. Heart normal, abdomen and extremities negative. Systolic blood pressure varied from 180 to 200, diastolic 120. The Wassermann was negative. An x ray of the chest was negative. The urine was loaded with albumin and casts.

The treatment was not changed, but during the next three days, an intensive search for antigenic factors was carefully made. Intradermal tests revealed several animal hair strong positives, including feathers,—but these had all been eliminated. Pollen tests were negative. As the patient for days had taken no food, dietary etiology seemed improbable. The question then arose as to the possibility of drugs constituting the immediate etiological factors. Intense positive skin reactions were secured to morphine and atropine, especially to morphine. Both were at once omitted, on Fberuary 5th, and codeine substituted. That night the asthma was extreme, and when seen early the next morning, the patient's condition was desperate. She was markedly delirious, with frequent attacks of vomiting and diarrhea, and asthma intense, as it had been for hours. The systolic blood pressure was 200. Intracutaneous tests were then made for codeine and heroine and found intensely positive, far more so than the usual positive reactions ordinarily secured with these substances in nonallergic individuals. The patient's condition precluded testing with graduated dilutions of these substances. It had been learned the day previous, that for some years past, she had been taking daily a well known codeine cough syrup for her bronchitis. This was of course stopped and all narcotic medication ordered withdrawn. On account of the urgent condition of the patient, almost exhausted from the extreme asthma, calling for immediate relief, and narcotics being unavailable, in view of the previous failure of epinephrin in twelve minim doses, it was decided advisable even if risky in the absence of any precedent to go by, to increase the epinephrin. As a last desperate resource, twenty-five minims of the drug in a single dose was slowly given. Almost complete relief immediately followed, the patient securing several hours of rest, the first for days. Blood pressure within a few moments fell to 170. By noon of the same day, relief was practically complete and the blood pressure had fallen to 140, where it remained. Epinephrin was continued in ten minim doses three times a day thereafter for three days, and then dropped to seven minims also three times a day. The patient was allowed out of bed only five days after the heavy dose of epinephrin, with both asthma and bronchitis gone, leaving the hospital in another three days. Albumin and casts disappeared from the urine a day or two after the cessation of the asthma, and remained absent. The immediate relief of both asthma and high blood pressure in this case following promptly a dangerously high dose of epinephrin was decidedly startling, as it was totally unexpected, and all sorts of trouble had been looked forward to.

Case II.—R. C., male, aged sixty-nine, single, a stockyard inspector for forty-five years, was first seen at Santa Rosa Infirmary on May 7, 1923. One year previously, he had been compelled to give up hard work on account of shortness of breath on exertion. He had been examined in Chicago and found markedly arteriosclerotic, with a systolic blood pressure varying from 200 to 260. His first attack of asthma was in December, 1922. He then spent one month each at the Mercy Hospital, Chicago, and at Mt. Clemens, without much relief. In the early spring of 1923, he had eight severe attacks of asthma. When first seen by me, he had been one month in the hospital in San Antonio, with constant unbroken bronchial asthma, and several severe intercurrent attacks. At the time of my first examination he was in a moderately severe attack which had lasted three or four days.

Examination revealed a person rather worn out and decidedly uncomfortable. Peripheral arteries were markedly palpable. the extremities, abdomen and reflexes were normal. Lungs showed the usual bronchial asthma findings. The heart was markedly enlarged with an accentuated second aortic sound and a loud diastolic murmur. The Wassermann was three plus. Previous urine examinations occasionally showed albumen and casts. The systolic pressure was 240.

While the general arteriosclerosis was obvious, the question of allergy arose. Skin tests at the time were impractical, as the patient demanded immediate relief. From his history and occupation, an animal hair type of asthma was suspected, so for a test, a heavy camel hair undershirt was held over his face while the heart examination was being repeated. Within a few moments, the asthma became extreme, the blood pressure rising to 260, and the patient's condition became critical.

The hospital room was at once stripped of feathers, wool, etc., in the usual manner. The patient years past had been a narcotic addict, and insisted that no drugs of that character be used. In view of the obviously extreme arteriosclerosis and high blood pressure epinephrin certainly seemed contraindicated. Remembering, however, the satisfactory experience with Case I, I decided to take another desperate chance. For two and one half hours, fifteen minims of the drug was given every fifteen minutes for four doses and then every half hour for two doses. At the end of that time considerable relief had been secured, the blood pressure dropping to 175. Four hours later, the dose was repeated with almost complete relief, the pressure falling to 170. Two days later, asthma returned, yielding to seven minim doses given every fifteen to thirty minutes for three hours.

For the next two weeks, small doses of epinephrin were given from three to four times a day, the patient doing splendidly in every way, the systolic pressure varying from 148 to 155. Epinephrin was then stopped, and iodide of potash was started in three grain doses every three hours. Several days of this treatment brought back some respiratory distress, causing the withdrawal of this drug and the resumption of epinephrin in five or six minim doses.

On May 26th he showed a mass of protruding hemorrhoids interfering with micturition. On June 3rd, a small area of gangrene was noticed in this mass, and hemorrhoidectomy was done under morphine and local anesthesia by Dr. L. M. Weinfield (cautery method). The operation was apparently well borne, and the rectum healed kindly. Hematuria, however, followed at once, with restlessness and drowsiness alternating for several days, attended by albuminuria and casts.

Iodide of potash in four grain doses was started again, and, as a result, extreme asthma suddenly returned on June 8th. Epinephrin had to be used in fifteen minim doses every hour for twenty-four hours before anything like relief could be obtained. Blood pressure again fell from 240 to 150 with relief from the attacks. The asthma then ceased, and did not return, permitting permanent withdrawal of epinephrin. The last attacks left the patient extremely exhausted. Edema of the ankles and shins commenced and persisted, along with marked dyspnea on the slightest exertion. The cardiac condition remained unchanged. Pulse rate, 80 to 100, regular. The systolic pressure remained around 145 to 150. A day or two later he became irrational. The mental condition grew rapidly worse, becoming maniacal about June 16th. While no evidence of asthma could be detected, the patient showed every evidence of renal breakdown, dying June 19, 1923. Autopsy was not permitted.

This case is reported merely as showing the influence of epinephrin on allergic high blood pressure, on not one, but consistently on several occasions, when invariably the relief to the asthma following the administration of the drug was accompanied by a marked fall in the pressure. While it is granted that there existed also in this case sufficient cardiovascular and renal disease to produce hypertension independent of allergy, the relief from the asthma and the coincident reduction of the blood pressure following epinephrin administration, makes for a decidedly probable connection between the two. I regret, of course, the necessity of an intercurrent surgical operation on a patient of this kind. Also the doses of epinephrin while apparently excessive, actually were no larger than was absolutely necessary to secure relief. Administration was very slow and stopped at once with the first signs of the abeyance of the asthma. Probably, antispecific treatment was also indicated.

Recently, in a third case of winter asthma of fifteen years' duration, in a woman of sixty-four, with a systolic pressure of 170, following the relief of her asthma by the removal of wool and feathers, her offending antigens, and the regular administration of epinephrine for a few days, the blood pressure fell at once to 150. It has for the last three months remained at 138, during which time, while undergoing immunization, there has been complete freedom from asthma, cough, and bronchitis.

In a fourth case, in a woman of sixty-one, complicated by a hemiplegia six months previously, a chronic asthma of many years' duration, whose antigenic factors were various danders, pollens and foods, and whose systolic pressure varied from 175 to 190—when first seen November 23, 1923,—removal of antigens, and the employment two or three times daily of epinephrin in three or four minim doses which cleared up the asthma, resulted within ten days in a fall in the blood pressure to 150, where it remained during the several weeks that the patient remained under observation.

However, the idea is not suggested that all hypertension accompanying bronchial asthma is necessarily invariably antigenic in origin. I have in my records one chronic perennial case, in a woman of sixty-four,—also of the combined animal dander and pollen type, with an original systolic pressure of 210,—in which the patient was relieved of her asthma and later successfully immunized in the usual manner. Her blood pressure, months later, is still 210.

CONCLUSIONS

Our knowledge of the causes of hypertension is far from complete.

Where this condition exists in connection with asthma or chronic bronchitis, certainly the question of allergy should be gone into. Immediate marked reduction of the high blood pressure coincident with the relief of the asthma following epinephrin administration suggests that cases of this type are totally or partially allergic in origin.

Also, apparently, from these few cases, high blood pressure in asthma is no bar to the use of epinephrin in even decidedly large doses.

Moore Building.

Report of Three Autopsies Following Carbon Tetrachloride Treatment.—J. F. Docherty and Lucius Nicholls (*British Medical Journal,* October 27, 1923) report their necropsy findings in three cases treated with carbon tetrachloride. A dose of four c. c. of carbon tetrachloride was given and it was found that fatty degeneration of the liver might be produced thereby. Although numerous fat globules may appear in the liver cells, the changes in the liver are of a temporary nature and do not appear to contraindicate the use of the drug, because many patients have been treated with much larger doses and have not complained of any discomfort other than very slight giddiness, nor have symptoms or signs of ill health arisen in them. Further, many hundreds of school children have received doses of carbon tetrachloride, and in no case has any sign of ill health occurred subsequent to treatment. In one case the changes in the liver were so marked that the signs of marked ill health during life were expected, but these were absent; consequently it appears that much fat (presumably derived from fatty degeneration) may appear in the liver and yet be a matter of small importance as concerns the health of the patient.

Practical Therapeutics

IODINE IN THE TREATMENT OF HYPERTHYROIDISM

J. Arthur Buchanan, M.D., M.S.
Brooklyn, N. Y.

The therapeutic advances of the last two years (1, 2) have shown iodine to have an important place in the treatment of certain types of hyperthyroidism, as well as in the prophylaxis of colloid goitre.

TYPES OF GOITRE

All types of goitre as ordinarily met are easily recognized by remembering the simple physical findings in the thyroid gland in goitrous individuals. There are three types of findings: 1, the smooth soft enlargement; 2, the smooth hard enlargement, and 3, the knotty hard or soft enlargement. Translated into terms of pathology the first type is called colloid goitre; the second type, exophthalmic goitre, and the third type, multiple adenomata with or without colloid, on which depends the consistency of the goitre. It is to be remembered that the last two types of goitre may occur in the same individual, and one or both may be active. This latter point is particularly useful in the selection of cases for treatment with iodine, as it is inadvisable so far as available information is concerned to administer iodine to a patient with hyperthyroidism due to multiple adenomata. This was clearly demonstrated in one of my patients suffering from multiple adenomata of the thyroid with hyperthyroidism, and in another with multiple adenomata and exophthalmic goitre.

INDICATIONS FOR IODINE THERAPY

Iodine may be with safety administered in all simple cases of colloid goitre. It may be given to any patient with exophthalmic goitre, but not to patients who have multiple adenomata with or without hyperthyroidism, for in the former the hyperthyroidism may be increased, and in the latter may be excited.

The form of iodine most frequently used in the treatment of hyperthyroidism of exophthalmic goitre is Lugol's solution, Liquor Iodi Compositus, U. S. P., but there is evidence to support the statement that any type of free iodine might be used (2).

ILLUSTRATIVE CASES

Case I.—Mrs. C. W. H., aged forty-five years, first came under observation on June 5, 1923. The essentials in her history were rapid heart action, nervousness, scanty menstruation for six months, weakness in the thigh muscles, gradual loss of weight with large appetite; sleeplessness; sense of warmth day and night; irritability, and fatigue on slight exertion. The pulse was rarely under 120. There was definite bilateral exophthalmos, a fine tremor of the hands, and a red tongue with many fine fissures. The thyroid was symmetrically enlarged with a palpable thrill, and audible bruits at all four poles. Each lobe measured four by two cm. The blood pressure was 160 systolic and 90 diastolic. The general physical examination was negative. The basal metabolic rate was plus sixty-five per cent.

The patient was put to bed, quietness maintained, ice bags placed over the heart and neck, and digitalis administered in fairly large doses. After a week the metabolic rate was plus sixty-five per cent. and there was no clinical improvement. The patient had had a previous rest treatment without any benefit. The patient was given after the last rest period one c. c. of Lugol's solution in a glass of milk three times a day. In two days she was positive that she felt better, and at the end of a week the pulse rate varied from 72 to 80 a minute when the patient was quiet in bed, and the metabolic rate had dropped to plus thirty-nine per cent. The dose was then reduced to 0.5 c. c. three times a day, and at the end of the second week there was some decrease in the size of the gland, and the eye signs were less definite. The metabolic rate was plus nineteen per cent. The patient was allowed up, after which the pulse ranged about 90 a minute. She was taken off iodine several times by her physician, but always the hyperthyroidism became more marked at the end of a week to ten days, and she would be relieved by going back to the iodine.

After several months of this treatment, the patient had a partial thyroidectomy, which had been preceded by a bilateral ligation of the superior thyroid arteries, from which no benefit was obtained. Following the thyroidectomy, the symptoms of hyperthyroidism were in abeyance for a few weeks, and then returned. The patient has continued to take almost constantly three or four drops of Lugol's solution three times a day, as it is the only way that she can be comfortable. Without it her metabolic rate goes up, and with it the rate comes down. Lugol's solution has been of distinct advantage to this patient, who had clinically and pathologically a true exophthalmic goitre.

The type of patient to whom Lugol's solution should not be administered, although an exophthalmic goitre is present, is illustrated in the following case:

Case II.—Mrs. V. K., aged thirty-six years, first came under observation on January 15, 1924, because of nervousness, rapid heart action, and prominence of the eyes. She had menstruated irregularly for several months. About five months before coming under observation she began to lose weight, although she had a large appetite, and her heart action was rapid. She became weak in the thigh muscles, and found going upstairs difficult. She was irritable and could not stand any noise. She perspired freely and felt very warm. At the time of examination there was decided exophthalmos in both eyes. The pulse was 130 a minute, and the blood pressure was 140 systolic and 70 diastolic. The thyroid was large, smooth and hard, with bruits at both upper poles and over the body of the gland. The lobes were three by two and a half cm., and the isthmus measured one by one cm. The heart beats were 150 a minute, and the muscle tones were faint. There was slight edema of the legs. The metabolic rate was plus 55 per cent. There were some small

nodules in both lobes of the thyroid. This patient was placed on one c. c. of Lugol's solution three times a day. In a few days she noticed that she was more nervous, the heart more rapid, and at the end of a week she was prostrated from weakness, the skin itched intensely, and during the last three days of the week she vomited frequently. The metabolic rate was plus 65 per cent. The Lugol's solution was discontinued, and her general condition returned in twelve days to its previous state. This patient was relieved of all her symptoms by a partial thyroidectomy, and the gland showed multiple adenomata in the presence of exophthalmic goitre.

The ill results of giving Lugol's solution to a patient with hyperthyroidism due to multiple adenomata is shown in the following case:

Case III.—L. B., female, aged fifty-three years, was first seen on January 12, 1924, because of nervousness. She had been sick for over a year with rapid heart action, weakness, nervousness, restlessness, and gradual loss of weight. At the time of the examination multiple adenomata were present in both lobes of the thyroid, which measured on the right five by three cm., and on the left two and a half by three cm. The blood pressure, which was probably affected by other factors, ranged from 200 to 140 systolic, and 120 to 100 diastolic. The metabolic rate was plus 25 per cent. After two weeks rest in bed the metabolic rate was plus 15 per cent. The pulse was less frequent, and the nervousness had decreased. Lugol's solution was then given in one c. c. doses three times each day, and at the end of five days the patient was worse than at any time since she had been ill, and the metabolic rate was plus 30 per cent. The Lugol's solution was discontinued, and in two weeks the patient had regained her former state of health. The gland removed by partial thyroidectomy showed multiple adenomata.

COMMENT

Although striking improvement is shown in many cases of exophthalmic goitre by the administration of Lugol's solution, there is probably no cure in the treatment. The patients, however, all stand operations much better by a preliminary reduction of the state of hyperactivity by the treatment. The danger of exciting a greater degree of hyperthyroidism in patients by the use of Lugol's solution necessitates a certain nicety in the clinical examinations that must supersede a diagnosis based purely on metabolic studies. I have used Lugol's solution in the treatment of a number of my patients with exophthalmic goitre, and in all there was some improvement, while in eighty-five per cent. the improvement was striking. It is a valuable addition to our therapeutic armamentarium in the treatment of this type of goitre, but apparently should not be given to the adenomatous subjects.

BISMUTH IN THE TREATMENT OF SYPHILIS*

By Hans J. Schwartz, M. D.
and Oscar L. Levin, M. D.
New York

(*Concluded from page* 550)

ACTIVE TERTIARY SYPHILIS

Case XXXIII.—M. S., No. 22568, male, aged fifty-seven, furniture mover, married, was admitted to the Cornell Clinic November 3, 1921, with spondylitis, arthritis deformans and a four plus Wassermann. Course of six salvarsan and fifteen mercury injections. Wassermann, May 5, 1922, still four plus. Second course of twelve salvarsan and eight mercury injections. Wassermann, August 8, 1922, four plus. Course of ten neotrepol injections which had to be discontinued because of severe stomatitis. Wassermann still four plus.

Comment.—Serology showed no improvement after sixteen arsenic and twenty-seven mercury injections. No conclusions can be drawn about the possible effect which bismuth may have had on the serology, since these treatments had to be discontinued on account of stomatitis.

Case XXXIV.—E. F., No. 17603, female, aged thirty-four, married, admitted to the Cornell Clinic on September 18, 1922, with large tuberoserpiginous, ulcerated syphiloderms, covering the left cheek, auricles and part of the scalp. Had received potassium iodide when first infected, and six months prior to admission had received six injections of mercury. Wassermann, September 18, 1922, four plus. Course of twelve neotrepol injections. Wassermann, October 20, 1922, still four plus, but there was marked improvement in the lesions, which became almost completely healed. Second course of neotrepol injections. Wassermann, December 24, 1922, still four plus. A third course of neotrepol was given. Skin lesions had completely healed and only the scars remained. A fourth course of neotrepol injections resulted in a two plus Wassermann reaction. The patient discontinued treatment.

Comment.—In view of the favorable result obtained in the disappearance of the lesions after the use of bismuth and the final reduction of the Wassermann test to two plus, we feel that this case shows definitely the benefits derived from bismuth in the active tertiary stage of the disease.

Case XXXVIII.—A. R., No. 22489, male, aged thirty-two, unmarried, elevator operator, admitted to the Cornell Clinic September 20, 1921, complaining of gumma of the left testicle. Had chancre in 1917. Wassermann, September 20, 1921, three plus. Twenty-one arsenic and thirty-five mercury injections given. Clinical symptoms cleared up. Wassermann, still four plus. Twenty neotrepol injections. Wassermann, November 21, 1922, two plus. Twelve neotrepol injections. Wassermann, negative. Third course of neotrepol injections. Wassermann, January 15, 1924, one plus.

Comment.—In this case the bismuth had a decided effect upon the Wassermann reaction, reducing it from a four plus to a final one plus.

*From the Department of Dermatology and Syphilology, Cornell University Medical School and Clinic, New York City.

SYPHILIS OF THE NERVOUS SYSTEM

CASE XLI.—L. M., No. 5283, aged fifty-two, male, unmarried, bookkeeper, admitted to the Cornell Clinic on January 6, 1922, complaining of deafness, Examination revealed cerebrospinal syphilis with involvement of the auditory nerve and a three plus Wassermann. Course of six salvarsan and twelve mercury injections. Wassermann became negative. Spinal fluid examination, August 22, 1922, showed cell count of 20, strongly positive globulin test, colloidal gold curve of 3344333200, Wassermann two plus. Course of sixteen salvarsan and twenty-two mercury injections. Blood Wassermann, January 2, 1923, three plus. Twelve mercury injections. Wassermann became negative again. First course of thirteen neotrepol injections. Wassermann negative. Spinal fluid showed decided improvement, in that the globulin test showed only a very slight reaction, cell count was only 7, colloidal gold test 0122342000 and Wassermann test three plus. Second course of twelve neotrepol injections. Wassermann, October 23, 1923, negative. Third course of neotrepol injections. Wassermann still negative.

Comment.—This case shows the benefits derived from bismuth in a case of syphilis of the nervous system, where subsequent to neotrepol injections, the Wassermann became negative and the spinal fluid reacted less markedly.

CASE XLII.—G. T., No. 7713, male, aged forty-four, married, waiter, admitted to the Cornell Clinic February 14, 1922, complaining of failing vision. Had previously received six salvarsan and six mercury injections. Showed on admission beginning atrophy of the optic nerve. Wassermann, February 14, 1922, four plus. Received thirteen salvarsan and eighteen mercury injections. Wassermann, January 31, 1923, three plus. Course of twelve neotrepol injections. Wassermann April 11, 1923, two plus. Course of six salvarsan and twelve mercury given after neotrepol injections because of stomatitis. Reaction after that was plus-minus.

Comment.—In this case the neotrepol seemed to aid in reducing the Wassermann reaction, but patient had to discontinue bismuth therapy because of stomatitis.

CASE XLIV.—S. O., No. 18306, female, aged fifty-nine, widow, moving picture actress, admitted to the Cornell Clinic August 15, 1922, complaining of pain and stiffness in legs and lower part of back, and stomach trouble. Had taken pills thirty years ago. Examination showed irregular pupils. Blood Wassermann August 21, 1922, four plus. First course of eight salvarsan and thirteen mercury. Wassermann, December 18, 1922, four plus. Second course of four salvarsan and twelve mercury injections. Wassermann, April 16, 1923, one plus. Third course of six salvarsan and ten mercury injections. Wassermann, September 8, 1923, one plus. First course of neotrepol injections. Wassermann negative, November 5, 1923.

Comment.—Four plus Wassermann was reduced to one plus after eighteen salvarsan and thirty-five mercury injections and remained one plus. After twelve neotrepol injections, however, the Wassermann was reduced to negative and all clinical symptoms disappeared, showing the advantage of having used bismuth in this case where the Wassermann reaction yielded at first to salvarsan but finally remained fast at one plus, until through bismuth therapy it became negative.

CONCLUSIONS

As a result of our observations for a period of over two years in the use of bismuth in antisyphilitic therapy, and with our opinions crystallized by the facts contained in the presentation of these cases[1] as well as from a study of numerous other dispensary and private cases, we must conclude that bismuth is a valuable drug to be employed against syphilitic infection.

This drug is of particular value in combating the spirochetal invasion when there is unusual resistance to the action of or intolerance of other drugs. Bismuth may be employed independently, or combined with arsenic or mercury, or arsenic and mercury. It seems to have less spirocheticidal power than arsenic but more than mercury. Its administration does not seem to interfere with the natural immunological powers of the body and in this respect it is extremely valuable.

Our observations in primary syphlis prove that bismuth destroys the spirochetes in the chancre, causes cicatrisation of the lesion quickly, brings about a disappearance of the adenitis, and affects the serology favorably. Its use may abort syphilis, but it is not as reliable as salvarsan for this purpose.

In secondary syphilis bismuth therapy causes the disappearance of the local and general manifestations and reduces the Wassermann reaction. It does these more quickly and efficiently than mercury and there is less possibility of the development of a Herxheimer reaction or a neurorecidive as when arsenotherapy is employed. It has been used in the presence of jaundice caused either by the disease or by arsenic with success and without producing harm.

This drug is also of value in latent and active tertiary syphilis, neurosyphilis and congenital syphilis, but its action is slower in such cases than in the earlier phases. However, in neurosyphilis it has been noticed that there is an absence of signs of irritation as from arsenic and that there may be decided subjective improvement when there are no apparent objective, clinical or serological changes.

Bismuth has proved of special importance for patients with arsenical dermatitis, in Wassermann fast cases, and in obstinate or recurrent cases.

The disadvantages of bismuth are few. These are occasional and slight pain, the rare formation of a black line on the gums and hypertrophy with black pigmentation of the papillae on the dorsum of the tongue. Some kidney irritation and cases of stomatitis were encountered, but these were comparatively rare.

It is obvious that bismuth constitutes another active antisyphilitic weapon in the armamentarium of drugs for the treatment of syphilis in all stages. In view of our conclusions, based on the facts presented, we feel that it must be accepted as a valuable adjunct in the treatment of syphilis.

Phosphorus Therapy.—At one time phosphorus played a very important part in medicine, but of late years it would seem not to have received due recognition, taking into consideration its usefulness in therapeutics. It is perhaps in the laboratory that most attention has been paid to it, and this can be understood, since numerous investigations in connection with phosphorus have explained various physiological and, indeed, pathological processes. And today, especially among the younger school, research in biological laboratories in connection with phosphorus seems to attract many investigators. Its disuse in medicine may be due to some extent to the fact that phosphorus, when administered as such, may readily give rise to toxic symptoms. On the other hand, the hypophosphites, from the exhibition of which so much was expected at one time, have partly lost their high place as therapeutic agents, and it is now generally held that they have little, if any, influence on nutrition, which fact can be readily understood when it is considered that practically the whole quantity of hypophosphites administered can be recovered from the urine in an unchanged condition. Later, the glycerophosphates held a high place, but they, too, have scarcely maintained their position in therapeutics.

Consequently, it is a matter of interest to come across a preparation of phosphorus in organic combination which presents the drug in a nontoxic and readily assimilable form. Phytin, a double salt of calcium and magnesium with inositol hexaphosphoric acid, has been shown (*Lancet*, July 8, 1922) to contain at least twenty-two per cent. of phosphorus. As its name indicates, phytin is obtained from plant seeds, and it is interesting to note in this connection that Posternak, of Geneva, has demonstrated that inosite phosphoric acid, prepared synthetically, is identical with the phosphoorganic material of green plants. Although the preparation was introduced twenty years ago, when its therapeutic uses were described by Prof. A. Gilbert and Dr. A. Lippmann, (*La Presse médicale*, No. 73, 1904) it does not appear to be generally known. The need of phosphorus in many conditions is very great, on account of excessive loss, or by reason of defective nutrition. In the opinion of Manquat (*Treatise of Therapeutics*, vol. ii, 1912) it is the most assimilable of all phosphorus combinations, and it has been shown by the French observers to act as a powerful stimulant of nutritive metabolism. Clinically, this action is manifested by a pronounced increase of appetite after a few days' treatment. Combined with quinine in the form of quinine-phytin, which contains fifty-eight per cent. of quinine, phytin not only counteracts the depressing effect of quinine, but enhances the specific action of this alkaloid. Quinine-phytin would, therefore, appear to be particularly useful in malaria.

Thorium Emanation in the Treatment of Chronic Leucemias. — Cluzet and Chevallier (*Bulletin de l'Académie de médecine*, May 13, 1924) administered by inhalation thorium emanation from the radiothorium contained in the sediment of the Echaillon spring water. An apparatus was constructed enabling the patients to inhale air passed through a thin layer of powder containing radiothorium and absorb a definite amount of the emanation. The average amount of emanation taken in a minute corresponded to 0.6 electrostatic unit. The duration of each course of treatment was fifteen to twenty days, the patient inhaling the emanation for two or three hours daily in divided periods of one half hour. Rest periods of at least one month should intervene between successive courses of treatment. In two cases of lymphatic leucemia the emanation alone proved capable of increasing the number of erythrocytes, reducing the leucocytes, and causing a striking improvement in the general condition and reduction of the glandular masses. In three cases of myeloid leucemia the fever subsided as a result of the treatment and there were the same effects on the red and white cells as in the lymphatic cases. The action of the emanation in reducing the leucocytes seemed to be less marked than that of the x rays, but the action in increasing the red cells was more marked. Combination of the x ray and thorium emanation treatments is advised.

Surgical Treatment of Intermittent Claudication (Operation of Leriche).—Hermann Schlesinger (*Wiener klinische Wochenschrift*, March 27, 1924) recommends Leriche's pariarterial sympathectomy for severe cases of ulcers on the lower extremities or in intermittent claudication due to angiospasm. In seven of his cases the results were favorable and in two cases a secondary amputation was necessary. The failures show that careful after-treatment for several months is absolutely necessary and that the extremity must be carefully protected from the effect of cold. The favorable cases show an improved circulation and a relief from pain a few days after the operation. Internal therapy is necessary as an adjuvant. Amputation may be avoided in this way. In addition to the use of sodium nitrite, the author recommends injections of the following solution: scopolamine hydrobromide 0.00025, dionin 0.03, morphine hydrochloride 0.02, in distilled water 1 c. c. for the pains occurring after the operation.

Historical Medicine

Galen's Commentaries on Kidney Disease

JONATHAN WRIGHT, M.D.

Pleasantville, N. Y.

We have seen ample evidence how pernicious was the prohibition formulated in the Hippocratic Oath which prevented Hippocratic surgeons from cutting for stone and that it had long been an interdict of ethics for them if not a law of the state. Just how this came about I have never been able to discover. It was but the prelude of all surgery passing over into the hands of the barbers. However, in the time of Hippocrates there is every evidence the surgeon, probably undifferentiated from the physician, used the knife boldly in other kidney disease, though even in Homer there seems a beginning specialization in the two sons of Aesculapius, who went to the Trojan war. However that may be, we have reason to believe, I think, that general surgery was in the same hands as pills and plasters in the time of Hippocrates. His were not the people and his was not the age when they dwelt in monster cities.

Specialization was impossible in the towns and the countrysides of Greece, the Asiatic littoral and the isles of the Aegean. When, however, in the lapse of ages and the shifting of civilizations we meet Galen, the denizen of a mighty city and the citizen of a mighty empire, crowded with people dwelling in the most profound peace the world had ever seen, though working out a destiny of disaster, we find here as in Egypt of old with its teeming cities the division of medicine and probably of other arts into many specialties. Galen not only did not cut for stone, he did not cut for kidney abscess, he did not practise ophthalmology when he lived in Rome out of fear for the hostility of the ophthalmologists, but back in Bithynia he had written a book on eye diseases and practised surgery on the gladiators. In Rome, besides being a physiologist and anatomist, he was what we would call a practitioner of internal medicine (1).

Most of the kidney disease recognizable in his day, being of a surgical nature and calling for surgical therapy, there is no discussion of this aspect of it at all. He deals with its etiology, symptoms and pathology, but as for its cure there is little to be found except multitudinous prescriptions for dissolving stone in bladder or kidney and the regimen for avoiding its formation and for moderating the pains of acute attacks. We find, however, in him, as in many of us today confronted by the same conditions, an appreciation of the evils of specialization unavoidable as they seem to be at certain stages of civilization. In a commentary (2) on that part of the Cnidian Sentences which he found in the Hippocratic Regimen in Acute Disease which declares there are seven diseases of the bile, twelve of the bladder and four of the kidney, he says the authors of such opinions have written more than they have any call to do—such things being indeterminate and vague. He felt very evidently, too, that the dividing line between surgery and its specialties and the art of medicine was also vague and indeterminate, however careful he was not to encroach at Rome on the former. Back of them all lie certain systemic physiological tendencies and pathological defects his philosophy taught as clearly as ours teaches us and these certainly are vague and indeterminate. He knew how varied is the biology of man—what is one man's food is another man's poison. In his book on Hygiene (3) he says:

"I once knew a certain old farmer, more than a hundred years old, living in the country, most of whose nourishment was goat's milk, sometimes taken alone, sometimes pieces of bread soaked in it. Sometimes he mixed honey with it and sometimes pieces of thyme with the bread. Another man, who thought the reason for the old fellow's long years was the milk, suffered injury when he tried it. The pit of the stomach was oppressed and the right hypochondrium was distended. A certain other man having attempted to make use of the milk likewise, although he did not suffer at all (for he boiled the milk) from heart burn or fatty eructation, nor from a weight in the hypochondrium, in a week from the beginning he said he felt distinctly a heaviness of the liver. It seemed to him something was lodged in the right hypochondrium like a stone as there was a dragging feeling extending as far up as the collar bone. It was very evident therefore that the liver was obstructed in this case and that flatulence was present in the other. Besides I knew that after using milk for a long time stones had formed in the kidney. There was another man had injured and lost all his teeth. Many other things have resulted from the use of milk."

Here as elsewhere he emphasizes the occasional, if not the frequent, bad effects of milk in the diet and its tendency to obstruct the liver and form kidney stone, though he makes concession to goat's milk, this being thinner, but anything thick, like milk or flesh that is not firm, whatever is glutinous (4) we infer, is conducive to clogging the liver, increasing the weakness of the spleen and generating stone in the bladder as things resisting digestion in these organs.

Other things have cleansing power, soup or broth made from peas more than that made from beans, so much more that it has a tendency to dissolve stone in the kidneys, and it is the little peas which grew in his native land of Bithynia, towards which his heart is ever turning. The honey there rivals that of Attica. Melon seeds, figs and juniper, from which once we made gin as a staple diuretic, but largely for other uses, are useful. Cheese, unless it is fermented, is free from danger of stone formation, but the juice of it is very heating. Thick things combined with this are injurious, anything thick thickening the humors. Thus we get on the track of the

thought wrapped up in a humoral doctrine. Thick things, undigested and ripe for hardening, influence the humors to harden and form stone or tophi. In view of this line of argument it seems consistent to find ingredients of prescriptions for stone in the bladder and kidney in a work on family medicine (5).

The food then is the chief factor in the Galenic etiology of lithiasis. With us the water we drink, or the wine we drank, once was. I imagine it was because heat was so prominent in his mind as a theoretical cause of stone formation that Galen was impressed, before the days of statistics, with the frequency of its occurrence in children. It is possible, I suppose, it was more frequent then in children than it is now. Others are better judges than I of that possibility. Certainly it was prominent in the mind of Galen that heat is a cause of stone, and children felt warmer to his hand than adults. Nothing is more easy than for fallible man, however critical of the thories of others, to be misled by his own. We can perhaps understand why the young and those in the prime of life should have been thought to have more heat in their bodies, but just what the ancients meant by internal (6) heat and inborn heat and natural heat is not very clear and to some extent at least the terms seem interchangeable. "On account of the great heat in boys thick material loses by evaporation and forms stone." Not only does heat and the surfeit of the system, supposed to introduce superfluities into the blood, cause formation of stone but inflammation of the kidney.

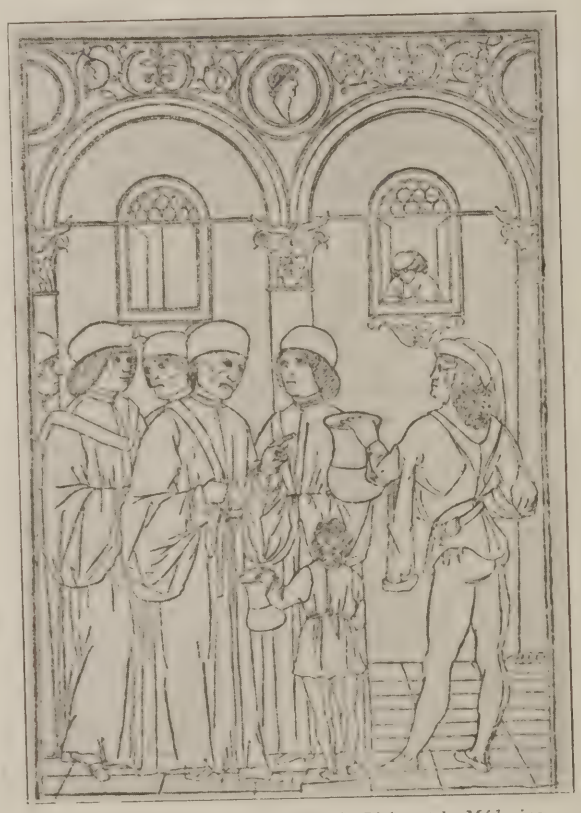

Fig. 1.—Uroscopy. From Richer's *L'Art et la Médecine.*

In the former connection Galen cites the sediment which collects in pipes and receptacles of water daily heated for the bath. Here we see a conception directly opposed to facts as they exist in the living body and an entirely erroneous analogy advanced from the inorganic. The heated urine holds the salts in solution and the urine ordinarily becomes cloudy and contains sediment on cooling, but for Galen the fundamental cause was the thickness of the humors however obvious his errors in the application of heat to his etiological theory. The guidance of Hippocrates is less obfuscated by theory. He quotes him in the discussion of stone in children in relation to their greater heat. Hippocrates, he cites, saying somewhere in his Epidemics: "Why, because warmer?" Why indeed? Galen from our point of view loses the point. The heat he thinks accounts for some of the thickness but not for all the viscidity of the humors. He had known children born with stone in the bladder. Some stress he lays upon the slender urinary passages in children, some to functional weakness and some to the indigestibility of milk. He becomes difficult to follow in the process, but he extracts from his argument that the urine in children is naturally thick.

The bladder being cold and bloodless and membranous and large, there is stagnation and the urine is not kept flowing. Children gorge themselves. They take milk at their mother's breast. They eat cheese, and all these things tend to thicken the urine. Speaking of thread and flake like bodies in the urine, as mentioned by Hippocrates in his Aphorisms, he conjectures such patients have been making use of "thick humoral meat" (7). We get the drift of his thought starting with the observation that high living, a surfeit of food and alcoholic drink is a fertile cause of kidney disease as a part of the lesions of circulatory disturbances. Surfeit is a good term for it and we are willing to allow superfluities in the urine, but the surfeit of food as a cause of disease we find not first in Hippocrates, but among the oldest of the traces of medicine we have of the Egyptians we find that is their conviction. Hippocrates does not lose sight of it but treats of it in sane fashion. Galen overstraining the theory of the humors is led into absurdities and distortions of fact and self contradictions. This mass of error was bequeathed to later generations and medicine had it as a heritage for more than 1500 years—the blight of a theory, which seems to have been coeval in its birth with this most ancient of all clinical observations of the cause of disease. Some there were who introduced the pneuma into the etiological chain and Galen, obsessed as he was with the doctrine of the humors, does not lose sight of it (8), but to this part of Hippocratic theory he gives little development.

Naturally in the symptomatology we get even a greater preponderance of the surgical kidney than is brought to our attention in studying the Galenic conception of the etiology, but nevertheless we get glimpses of disease of the kidney other than the surgical affections, impossible as it is to separate the discussion of them. As may be imagined from what has already been said, there is hardly an objective or a subjective sign that Galen does not associate with some divagation of an humoral etiology and

pathology, but there are some he records which seem to fall outside of this category. The surest signs of ulceration of the kidney are small pieces of flesh coming away in the urine, being part of the substance of the kidneys. From its association in the context we may perhaps think of a blood clot, but he seems to think it tissue torn from the edge of some gnawing ulcer and he turns to the Aphorisms of Hippocrates to annex to this condition the phenomena of the long threads seen also in the urine of some patients. These, he declares, are more probably from the veins. He likens them to helminths in color and size as they are described by others, but "not having seen them myself I have nothing to contribute either concerning their genesis or definite structure." If he has failed to note such things a span long and so large as described, he thinks these correspond in nature to the hair like threads he supposes come from the veins, though he is at a loss to account for the length of them, but he has seen them without any sign of kidney or bladder disease. Despite the contiguity of these phenomena, as they lie in the text, the threads and the flesh like bodies were not of equal significance (7). Despite his assurance the latter are the flesh of the kidney, he thinks of clots of blood. At any rate, he is sure they are not and that Hippocrates did not mean to say they were of the same nature as the threads.

Flakes in the urine, he agrees with Hippocrates, come from a furfuraceous inflammation of the bladder walls which like such affections of the skin he calls psoriasis, the small flakes having their origin in the veins and the large ones from the internal surface of the bladder. The pellicle of fat floating on the urine comes from a general liquidation of the fat in the body after a time, but when there is a fatty sediment it indicates a dissolution of the fat around the kidney or even in the kidney itself (8). In commenting on the lumbar pain he seems to think it a sign of inflammation of the muscles along the spine which spreads as does that of the adipose areolar tissue around the kidney to the organ itself. Thus there is no conception of kidney disease as part of a general vascular systemic disease, notwithstanding its etiological connection with overfeeding. He acquiesces in the advice of Hippocrates, "When they are full of food and have a heavy pain in the kidney they vomit phlegm. The pains are great and there is numbness in the thigh. The urine is dark colored and bloody with red sand in it. Rest does not help them or exercise drive away the pain, but the emesis gives relief. Give the young hellebore, bleed at the knee, clear them out with diuretics, diet and relax them." (9)

As to the pathology, some claim the stones are formed in the flesh of the kidney itself like the tophi of gout, but we are lost when he declares those who have sand and tophi in the urine show indications of having small swellings around the vena cava which soften and break down and from the pus the tophi form. They come out through the veins and enter the bladder with the urine. "Although this is the assertion of Hippocrates, it is not impossible the stones were formed in the kidney in the way I have described, baked hard with time and dried out of the thick and sticky humor they take on a tophoid structure." However, he is not unwilling to admit that the attractive force of the kidney is such that the sand grains may be forced through the walls of the veins (9). I fancy his thought is in his comments here on Hippocrates that, as he elsewhere declares (7), the passage of stone lacerating the kidney, the ureter and bladder, they may thus secure their exit from the veins. Blood of kidney origin and pus likewise as the result of the ulceration find their way into the urine. With these cases he was familiar as also with hemorrhage into the bladder, but it is not very intelligibly discussed, and though he has much to say of the purulent diseases of the urinary organs he does not discuss their surgical treatment at all.

The author's biblicgraphy will appear in his reprints.

Contributors to the Science of Medicine

Carlos Finlay

To have made a great discovery, to have fought to establish its correctness for more than twenty years, to have seen it accepted and put into practical operation for the benefit of humanity, and to have, therefore, been honored by all the world, is an achievement reached by few men. The son of a Scotch father, Carlos Juan Finlay inherited that clarity of vision and dogged tenacity of purpose, as well as the mental honesty which characterizes that hardy race. From a French mother he received the quality of imagination and the meticulous love of scientific detail and order, as well as the amiability and courtesy so typical of the French.

Born at Camagüey, Cuba, on December 3, 1833, educated by a Scotch aunt to the age of eleven, Finlay went in 1844 to Havre, where he remained two years, until obliged to return to Cuba on account of chorea. This was an affliction from which he never wholly recovered, and throughout his life he was afflicted by a peculiar slowness and hesitation in his speech. Returning to Europe in 1848, the unsettled political conditions existing in France at that time forced him to visit in London and Mayence, but the following year he was at school in Rouen, from which he was obliged to return to Cuba in 1851 in order to convalesce from an attack of typhoid fever.

Next he visited Philadelphia, where he was graduated from the Jefferson Medical College on March 10, 1855, and in the following year he went with his father, Edward Finlay, also a physician, to enter

practice in Lima. In this they were not successful, although a second attempt was made in 1857. In 1860-1861 young Finlay was doing postgraduate work in Paris; in 1864 he entered practice in Matanzas, Cuba, and in 1865 he married.

Finlay was essentially a student and a thinker, and as early as 1865 he was writing upon the etiology of yellow fever, with which he believed at that time the alkalinity of the atmosphere had something to do. This idea was not relinquished easily, and between that date and 1880 he wrote several papers on this subject.

Relatively few of those now engaged in the practice of public health have any knowledge of the National Board of Health, created by Act of Congress in 1879, and still fewer, of the International Sanitary Conference which was convened in the City of Washington January 5, 1881, largely through the efforts of that board. For more than twenty years there was not held another international sanitary conference in the United States. But had heed been taken of Finlay's words, uttered before the conference of 1881, the eradication of yellow fever would have been more quickly accomplished, and the world saved many lives and many millions of dollars. The doctrine which Finlay enunciated was revolutionary. It was a new scientific principle—one which had not been previously before the world. Beauperthuy, Nott and King had already expressed the opinion that mosquitoes had something to do with yellow fever. It is extremely doubtful if Finlay had any idea whatsoever of what they had said. They had not, however, reduced their opinions to a crystallized and workable epidemiological standard. The hypothesis to which Finlay gave utterance at the Conference of 1881, is as follows:

> It is my personal opinion that three conditions are necessary in order that the propagation of yellow fever shall take place:
>
> 1. The presence of a previous case of yellow fever within certain limits of time, counting back from the moment that we are considering.
>
> 2. The presence of a person apt to contract the disease.
>
> 3. The presence of an agent entirely independent for its existence both of the disease and of the sick man, but which is necessary in order that the disease shall be conveyed from the yellow fever patient to a healthy individual.

So far as the proceedings show, the announcement of this great scientific principle, which was to become the cornerstone of the entire combat of yellow fever, which was to make the building of the Panama Canal possible, which was to relieve humanity of a terrible scourge and commerce of an expensive impediment, passed practically unnoticed and undiscussed.

To a man of more brittle character, and less scientific tenacity, this would have been a crushing blow, but on August 14, 1881, Finlay presented to the Royal Academy of Medical, Physical and Natural Sciences of Havana, Cuba, a paper on "The Mosquito and Yellow Fever." Thirteen members of the Academy were present on that momentous occasion, and the minutes of the meeting do not disclose any discussion, although the Secretary-General announced that Dr. Finlay's work was at the disposal of the members who desired to examine it and make any suggestions on further studies. In this paper Finlay recorded his studies on the excessive alkalinity of the atmosphere of Havana, and its conjectural relations with yellow fever; he discussed the theories of the origin of propagation of the diseases, the atmospheric, miasmatic, meteorological, and other conditions hitherto supposed to play a rôle in the spread of the disease. Then follows a careful biological study of the mosquito, noting particularly that it is the female which bites in order that her eggs may be fructified; and as a final proof, Finlay records experiments which were made on five persons, in an attempt to prove whether or not yellow fever may be transmitted by the bites of mosquitoes. Of these five, one suffered a typical case of benign yellow fever; two had yellow fever in an abortive form; and two light ephemeral fevers of undetermined character.

There followed the work of years in the development of his hypothesis, and with the outbreak of the Spanish-American War, and although he was sixty-five years of age. Finlay took part in the campaign around Santiago. On his return to Havana in 1898, he brought his views to the attention of the officers of the American Army, the Cuban Government, and the medical journals of the United States. Generous, and desiring only that the world should profit by his labors, he cooperated wholeheartedly with the United States Army Medical Commission, headed by Walter Reed. Then, finally, the proof of his doctrine was made clear.

In 1902 he was made Chief Health Officer, and president of the Superior Board of Health of Cuba. Scientific honors of every sort were showered upon him. In 1909 he was appointed honorary president of the National Board of Sanitation and Charities, with a salary of $2,500 a year for life, and on August 20, 1915, the life of this great physician and scientist was closed.

Thanks to his indefatigable industry, his accuracy of observation, and his brilliant deductions, the weapon of eradication was placed in the hands of the field worker, and today the monument to mark the fact that Carlos Finlay lived and worked is the almost complete world extermination of an epidemic pestilence, the "jaundiced handmaiden of death," who in other years laid her deadly fingers on many a town and city, throttling its commerce, terrorizing its inhabitants, and bringing to premature dissolution the youth of the community.

Albert Schweitzer — Missionary, Musician, Physician.—Dr. Oskar Pfister (*Neue Zürcher Zeitung*, April 17 and 18, 1924) tells us that Albert Schweitzer is like the rainbow which gleams in every color, yet maintains a magnificently complete unity. It is his opinion that no living man has given significant literary expression to such a variety of talents. Schweitzer first came before the public when the violent storm was raging over his revolutionary works on the life of Christ and of Paul. His knowledge, ability and brilliance were unquestioned, but there was hardly anyone to agree with him in his opinions and ideas. His next essay was in the field of philosophy, especially that of Kant, where he seemed to outdo the master in absolute abstraction and remote intellectualism—until his two volume work on the philosophy of suggestion dem-

onstrated the contrary. The next works of this prolific and complex personality were on the history of music, and his monumental work on Bach and his edition of his fugues roused the admiration of all musicians who knew them, as did also his book on organ building in France and Germany. His first medical work was the famous *Psychiatric Judgment of Jesus,* soon followed by another philosophical contribution entitled *Between Water and Forest,* in which the ethnologist, the sociologist, the missionary, and the teacher joined forces in defense of the spirit.

But it is evident that literary productivity represents only part of Schweitzer's unique personality, writes the author. Over and above the scholar and the artist stands the man himself, intensely alive and governed by high ideals. When he was thirty, even at that early age overwhelmed with scientific and artistic successes, he was brought through the reading of a pamphlet to a lightning decision to take up the study of medicine. He sacrificed all his artistic triumphs and promise of a career, and devoted himself entirely to a thorough preparation in this study. When this was completed, he disposed of his art collections and went out as a medical missionary to the blacks of the Ogowe in Africa. "Here," writes Pfister, "he worked throughout days of burning heat in a shed of corrugated iron which he had had built, as a joke, precisely on the equator, occupied from morning till night with operations and the other duties of a physician. In the evening he would open up the sheet iron case that protected his beloved organ from the white ants, and solace and refresh himself with music, or would work on the history of civilization which he is writing. Forced out of his field of labor by the war, he seasoned his long captivity by committing to memory Bach's works for the organ, drumming with skillful fingers on his table and tapping on the floor with his feet to heighten the illusion. At the conclusion of the war, his lectures on mission work and the organ won a new place for him, and as soon as he could collect sufficient funds, he set out again for his African forest. Today at forty-nine he is journeying again to Africa in the hope that for some years to come he will retain the health necessary to carry on his arduous labors. To material possessions he is indifferent. His hope is that in his old age he may work and die as organist in an Alsatian village."

The writer goes on to tell us of a little biographical work by Schweitzer recently published entitled *Aus Meiner Kindheit und Jugendheit,* the outcome of a request by Pfister that he should furnish him with biographical material for a juvenile edition of *Between Water and Forest.* Pfister describes this little work, of which he received the first published copy, as plain, simple, and adorned with droll humor, in spite of the deep feeling with which it is written. He has kept the heart of the child in its best sense. Dr. Pfister is of course intensely interested in the psychology of the book, showing how the author's whole later development was conditioned and anticipated from his earliest childhood. His love of animals, which is given in Schweitzer's philosophy of life a prominent place, arose from a touching experience with an acquaintance who enjoyed hunting, and whom the lonely little boy would have been glad to have for a friend. Early one Sunday morning they met in a meadow where they were to hunt birds with a sling shot. But little Albert, as soon as the church bells sounded, could stand the sport no longer, and ran at the birds to frighten them away, leaving the friend he so much desired to return to his familiar loneliness. He thus learned compassion for animals, and to have no fear of human beings.

His sympathy for humans was aroused by watching a Jew who was accustomed to go through the village with a donkey cart, tormented by the children, but answering their taunts always with a good natured smile. "That smile won me," writes Schweitzer. "From that Jew I learned for the first time what it means to submit silently to persecution. He became a great teacher to me." His social conscience arose from a fight with a bigger and stronger boy. Albert knocked him down, but the boy retaliated by shouting, "If I had meat soup to eat twice a week like you, I'd be as strong as you are!" From that time Albert felt a disgust for meat soups. His social consciousness was awakened when he watched his uncle, after whom he was named, bringing milk during the siege of Paris to poor women.

His artistic abilities manifested themselves at an early age. At nine he could play the organ, although he objected strenuously to practising, preferring to improvise. Both his father and grandfather were musicians, the latter an organist.

Pfister attributes Schweitzer's remarkable versatility to a life of inner repression. The boy's earliest memory was a moment of terror in church when he mistook the organist with his bristling beard for the Devil. He had many other terrors in his early childhood. The mature man writes: "As far back as I can remember, I have always suffered so much from the misery I saw in life that I have never really felt real joy in living." Even the fact that every trifle made the boy laugh so that he was nicknamed Isaac, in Hebrew "the laugher," suggests hidden sorrows. Yet his childhood was a pleasant one and his parents were exceptionally intelligent and understanding. But they suffered much from poverty and sickness, and his mother was so reserved that she could not express her love outwardly, and this trait was handed down to little Albert. But, Pfister declares, all these hypotheses make only a patchwork of his remarkable life; no analysis can reveal the secret of such a personality. His father's recovery from a long illness, and his consequent joy in his companionship and in life itself, made the youth resolve at twenty to study science and music and to devote himself directly to the service of mankind. His career as a missionary physician was the culmination of these desires and his studies.

Dr. Pfister concludes his article with a most interesting summary of his analysis of Schweitzer, whom he calls "one of the most modern of modern men, sacrificing all that he had to the same purpose, who struck out into the primitive African forest, there to labor with incredible devotion on behalf of his bitterly suffering brethren—not as one who flees the world, but as one who desires to enlighten the world and to enrich its civilization; not as one who denies life, but rather in the spirit of one who seeks by every effort to help forward Christendom as the kingdom of God."

Editorial Articles

MUSIC AS MEDICINE

And David played before Saul, but it did not cure, nor did it seem to relieve, the headache (due, doubtless, to acromegaly, for Saul was a giant) or other symptoms of which the king complained. Possibly Saul had no taste for music and this new cure was advised by his courtiers as cures are now advised (or ill advised) by neighbors and even chance acquaintances. Possibly David did not play music of the right sort and, so, brought on himself, by lack of wisdom in selection, a narrow escape from death.

Periodically, music is advocated as a cure for disease. For over a century it has found a place, particularly in France, in the treatment of nervous and mental disorders, and marvelous results have been claimed from its use. That music exerts a profound influence, nervously or mentally, upon many persons there can be no denying; and if it influences the well, it also influences the ill. Whether it can produce cures is another matter, and might depend not only on the definition of disease but on what we may call a cure.

It has been tried in connection with dentistry and even as an adjunct to the operating room. Certainly in many cases it is a great comforter—a great distraction from other and less helpful lines of activity—and, so, beneficial. It helps to pass the time pleasantly and objectively and that, after all, is the main issue in an invalid career. It has recently been made use of in the hospitals, both general and special, of New York city on an organized and extensive scale, and it must certainly be worth all it costs. At one time a musical clinic was established in New York, at which patients could receive treatment and an elaborate therapeutic list of musical compositions was devised. It has been used in many hospitals for the insane with good effect in calming and entertaining these patients, and its adoption as a means of changing the nature of criminals has been seriously considered by a national organization which interests itself in the conduct of prisons.

Many studies have been undertaken to find the physiological effects of music—the definite functional changes which go on as a background for emotional results. The pulse and respirations have been found to be quickened by martial strains and slowed by minor melodies, and the effects on fatigue have been noted. The latest of the laboratory checkings of what has always been known empirically, is on the effects upon electrocardiograms and blood pressure. As carried out by Ida H. Hyde of the University of Kansas, "the plan was to compare the effects of vocal music and that of different native endowment and training and under varying conditions, but only a beginning was made—enough, however, to prove that investigations in this field offer important returns." It was found that "most people are favorably affected, psychologically and physiologically, by music that is characterized by tragic, mournful tones, and favorably affected by gay, rhythmical rich toned harmonic melodies. Individual differences in native endowment and training are accompanied by individual differences in physiological reactions to certain musical compositions.

The indications are, that those selections of music rendered either vocally or instrumentally that exert a favorable reflex action on the cardiovascular system, have also a favorable influence upon the muscle tone, working power, digestion, secretions and other functions of the body."

Among other experiments, a lullaby was played on a violin for a woman "who appeared to suffer from nutritional disturbances as a consequence of influenza." The electrocardiogram showed a disordered heart action with auricular flutter. "Both her husband and the experimenter were amazed at the suddenness of change in the cardiac contractions when the lullaby was heard. In some of the tests the deflections of the flutter decreased, in others they apparently ceased. The systolic and pulse pressures and relative velocity of blood flow were increased, but the pulse rate and electromotive force of the ventricular muscle decreased. The musical tones proved restful and beneficial to the patient."

THE CARE OF INFANTS

Regarded from one point of view infants are better cared for, at the present time, than at any other period. Considered from another aspect they are not so well cared for as was formerly the case. The infants of the poor and especially of the indigent, are better nourished and looked after than in bygone times. On the other hand, the infants of well to do and of fairly well to do people have not the advantages which those of a few decades ago possessed. Breast feeding with an unfortunately large proportion of mothers in easy circumstances has fallen into disfavor and there is no need here to dwell upon the superiority of breast feeding over any other kind of feeding for young infants. Except in a comparatively few cases mother's milk is the best food for infants.

But hospital service to infants has improved

beyond belief, that is, in most countries. In Italy there is a foundling hospital, the Spedale di Santa Maria degli in Florence, which is said to have been in continuous service for almost five hundred years. This hospital is housed in one of the first buildings of Renaissance architecture, the loggia of which is decorated with *bambini* infants in swaddling clothes, by Andrea della Robbia. This was the first institution of the kind in Italy. Perhaps the most scientifically arranged and managed is the magnificent institution in New York under the direction of Dr. A. F. Hess, in which many infants are brought up in glass cubicles to protect them from infection, being moved at intervals to open solaria to receive the benefit of unfiltered sunlight.

In London, there is the Infants' Hospital in Vincent's Square, which, under the directorship of Dr. Eric Pritchard, is beginning to make headway against the many difficulties, financial and otherwise, which are inherent in the management of all such places. The London Infants' Hospital is a notable institution, both inpatient and outpatient departments are well built and arranged for the purpose and ideally situated. The inpatients' department will house in the neighborhood of thirty babies in the public wards without the least overcrowding, and there are also eighteen smaller rooms for isolation or for special cases. The inpatients' department is suitably equipped in every respect. The outpatients' department and nurses' home is in a separate commodious building close to the institution itself and providing accommodation for a very large number of infants.

The largest foundling hospital in the world is that in Moscow. All these institutions are doing good work and wherever and whenever possible the babies are fed at the breast. In the Florence hospital, in every case in which it can be done, mothers nurse their infants, and as striking evidence of the good effects of this natural proceeding, it may be said that in the stupendous Foundlings' Hospital in Moscow, the death rate of the babies nursed by their own mothers, other conditions being the same, is one half of the death rate among those nursed by foster mothers.

Of course, too, in institutions in which infants are massed together, the greatest care must be taken to allow plenty of space and air. If not the results are deplorable. In the Infants' Hospital on Randall's Island many years ago, the results of overcrowding and possibly lack of breast feeding were appalling. The proper teaching and practice of infant and child welfare are saving life and bringing up healthy children, but emphasis should be laid on the point that breast feeding should be encouraged wherever possible.

SOME NEW DIAGNOSTIC SIGNS IN SCARLET FEVER

There are cases in which the diagnosis of scarlatina is difficult and where diagnostic signs must be carefully looked for. The elbow fold sign (Pastia) is important, because it appears at the onset of the eruptive phase and remains for some time after in the form of an intense linear ecchymotic streak. To detect it, the forearm is extended and by a slight upwards or downwards traction the skin of the elbow fold becomes wrinkled. This sign is positive in at least ninety-five per cent. of cases and never is present in other erythemata or eruptive affections. Besides, it is valuable because when the scarlatinal eruption has disappeared it will be the means of making a retrospective diagnosis, since it persists for some days afterwards.

Other signs of the ecchymotic series should be searched for. That of the elastic band consists in the production of petechiæ on the forearm when pressure of forty to sixty mm. is made with an elastic band above the elbow for from five to fifteen minutes. This sign is met with in diseases other than scarlet fever and when positive it does not imply that the case is one of scarlatina, but when negative in scarlatiniform eruptions, it can be assumed that the process is not scarlatina.

Hecht's sign is the production of petechiæ by pinching the skin. It is not specific, but when it is not produced, or only with difficulty, the case probably is not scarlet fever.

The cupping glass sign is an exaggeration of the eruption and the production of petechiæ over the area covered by the glass. In scarlatina the ecchymotic petechiæ are fine and irregularly scattered over the area and are not superposed on the pores of the skin, while in measles the cupping glass provokes quite a different geographical outline.

Up to the present time laboratory researches have been negative and the research for the deviation of the complement is still being studied. The phenomenon of extinction described by Schultz and Charlton is based on the principle that the serum of convalescent scarlatina patients—as well as normal human serum—has the property of causing the eruption to disappear, while it has no action on other exanthemata. Scarlatinal blood serum withdrawn during the height of the disease has no action on the eruption.

Serum properly prepared and kept in ampoules will remain active for three months. It is interesting to note that Debré and Paraf state that the serum of convalescents is indicated in the treatment of serious cases of scarlatina. It should be used at the onset of the disease or malignant cases; the serum treatment does not appear to have any preventive action

on the secondary infectious complications of the disease.

The serum is given in intramuscular injections in doses of from forty to fifty c. c., and repeated on the following days at the same or a slightly lesser dose. Intravenous injections, which may cause shock, should be resorted to only with great precaution and in desperate cases.

"CHILDREN'S" DISEASES

The death rate from scarlet fever, measles and whooping cough have declined to nearly one fourth of what they were four decades ago, notwithstanding that no specific treatment has been in use for these diseases. The period is such a long one that the decline in deaths from these causes seems to be more than a mere periodical fall in the virulence of the infecting organism. Either such a decline has taken place in a more lasting way, however, or we have been acquiring a steadily increasing ability to combat the disease, for the number of cases does not seem to have declined with the decrease in mortality. According to a recent report of the Public Health Service which is based on the records of over thirty-five thousand children, eighty-nine per cent. have had measles by the time they have reached adult years, while seventy-eight per cent. have had whooping cough, sixty-five per cent. mumps, and fifty-two per cent. chickenpox. Measles, mumps, whooping cough, and chickenpox seem to have been more frequent among natives than among the foreign born.

The fact that chickenpox, for which little is yet done in the way of isolation, is comparatively infrequent, does not strengthen the opinion that quarantine for the four diseases of the group is effective to any considerable degree. The probabilities are that, by the time quarantine regulations are brought to bear on these four diseases, they have already been communicated to companions. We may check an epidemic but there is slower spread later.

The incidence of scarlet fever was twelve per cent., and of diphtheria, nine per cent., and these figures would tend to reestablish our confidence in quarantine and to indicate that it is really effective in diseases of a more definite and acute onset. The blame for the high incidence of the first mentioned diseases is thus thrown on the nature of the diseases rather than on the lack of effectiveness of isolation. The lesson to be learned from these figures is that the prevention of infection is far more necessary than the prevention of the spread of infection and, happily, we seem to be on the way toward this method of stamping out these diseases.

It is interesting to speculate on the causes of the decline in the death rate of measles and whooping cough. Possibly better conditions of living would receive most credit for with better housing and more sensible clothing there is less likelihood of complicating lung diseases. Possibly improved milk supply and better care of the tuberculous adults may have had not a little to do with these declines, for who knows but that many of the deaths from these diseases were due to a lighting up of a tuberculous process in the young subject which was not recognized as tuberculosis. The diminishing size of families and hence the better care which each child receives in health and in sickness may have had not a little influence in enabling the child to overcome the infection. After all, there is much that we do not know about these still common diseases.

THE CAUSE OF RICKETS

Perhaps the cause of rickets is nearer its solution than ever before. Some state confidently that it is solved. Up to a few years ago it was regarded by most authorities as mainly, if not wholly, due to a dietetic deficiency, and so widely current, indeed, was this belief that by many it was classed as a vitamine deficiency disease. Others held that it was due not only to vitamine deficiency but to a diet deficient in other constituents essential to sound health, the mineral salts for instance; in fact, that the condition was owing to an ill regulated diet. At the same time it was conceded that unhealthy environment, lack of sunshine and so on, were important factors in its causation. Recently, however, the theory that lack of light was the principal cause has been gaining ground and according to certain investigators this point has been absolutely proved.

Paton and Findlay, of Glasgow, are the chief English speaking exponents of this view. Hess, of New York, also is of the opinion that the absence of sufficient light, especially of sunshine, exerts a maleficent influence on the growth and the bones of children. Investigations in Vienna, possibly the most hunger stricken city of Europe and therefore the one best calculated to afford favorable opportunities for experiments with regard to the rickets question, were carried on for a considerable period of time with satisfactory results. Dr. Pirquet, of Vienna, delved into the matter with no definite outcome. The Lister Institute of Preventive Medicine sent out a commission headed by Dr. Harriette Chick who conducted lengthy investigations. The most convincing of these were somewhat as follows. From the sweepings of the slums of Vienna, Dr. Pirquet collected for the Lister Institute Commission one hundred infants who were housed under ideal conditions. Fifty of them were fed on the Pirquet re-

stricted rations and fifty under the charge of the commission had full milk and some codliver oil. This experiment took place in the spring and summer when the days were long and light and there was a good deal of sunshine. At the end of the time all the babies were in splendid condition and it was hard to say which was a Lister and which was a Pirquet baby. The obvious reason for this was that the light and sunlight, in particular, had had a remarkable vitalizing effect, so much so that infants fed on a restricted ration but scientifically regulated except that it lacked codliver oil, flourished.

The next experiment began when winter set in, and in the absence of sunlight, the food and its quality was the dominating factor. The babies without codliver oil and other food constituents wanting in the diet of the Pirquet infants failed to put on weight —began to exhibit symptoms of rickets. Consequently, it seemed that definite proof had been given that the first tendency to rickets is imparted by deficient diet, but that this tendency can be neutralized by plenty of sunlight. In short, that the absence or lack of sunlight and proper food will bring about rickets. Moreover, investigations have shown that the ultraviolet rays will prevent or cure rickets and in a less degree will take the place of sunlight. This was proved in Vienna and has been proved in the slums of London and of other big cities.

Finally, it has been established that the primary cause of rickets is deficiency in the quality of the food, but that sunlight, or the ultraviolet rays, will effect such changes in a child's organism as to enable it to cope with the deficiency. The healthful influence of sunlight is striking. Of course, it stimulates growth and is quite as remedial in the case of surgical tuberculosis as in rickets. The latest discovery in this direction is the most remarkable. It is not essential that light be applied directly. If a volume of air is rayed, or if a piece of radium is suspended in it, the air itself appears to become possessed of healing properties. How the rays affect the air is not known. When this secret of nature is revealed we shall begin to understand better how and why climate affects health and disease.

The causes of a stunted and rickety population are partly wrong food and partly not enough light. It is difficult to exactly apportion the blame to one or other of these causes, and in spite of the assertions that the causation of rickets is definitely solved there are several points yet to be cleared up. People who live in almost continual sunshine, and not in tropical countries either, are not more healthy, if so healthy and vigorous as those who live in a temperate variable climate under favorable conditions so far as food and environment are concerned as in Great Britain, for example, or in Canada. There is an old and true saying that "one may have too much of a good thing," and this applies even to sunshine.

Is rickets prevalent in the cold dull zones of the earth? While a sufficiency of sunshine is absolutely necessary, suitable food is quite as essential and it must be a food which is adapted to the climate. The tendency nowadays is to eat too much artificially prepared and cold storage foods and not to give our jaws and teeth sufficient exercise. Further, babies, generally speaking, are given more food than they require and overeating as a cause of rickets is overlooked. Quality of food is of greater importance than quantity and diet still bulks large in the causation of rickets. Diet and light, combined with home environment, are the main causes of rickets as they are of many conditions of ill health. It should likewise be borne in mind that after all heredity is one of the most important factors with regard to good health, and especially with respect to tenacity of life. Man may not inherit many physical or mental traits or defects, but his ancestors are responsible, to a large extent, for the quality of his brains and physique.

DISEASE AND ITS TREATMENT

Conceptions as to the nature of disease have changed and are changing. While few, perhaps, will go as far as Mr. McDonagh that there is really only one disease, that is a battle between the body and invading organisms for free electricity, yet all will agree that disease is a question of the defensive powers of the body being at a low ebb and therefore unable to defend its territory in the strenuous way it would if the system were in a healthy condition. It is believed that the leucocytes are mainly responsible for the defense of the body and that if they are present in large numbers, its capture by the enemy is impossible. In proportion as ideas with regard to the nature of disease are undergoing reconsideration so of course are the views respecting the action of drugs. In the case of an infection it has long been held that a drug acted directly on the infection and that the ideal drug for which every chemist was searching eagerly was one which at one and the same time would destroy the invading organism and be harmless to the system. When salvarsan was first brought out it was hailed as such a drug. Longer experience seemed to show that it did not act in this manner.

The most recent theory of the therapeutic effect of drugs is that they act directly on the protective mechanism of the body. This is to say that if this be stimulated the invader is routed, but if it be destroyed the invader gains the day. Therefore the

drug does not attack the disease directly but marshals the defensive forces and stimulates them to increase the resistance of the body. In a paper contributed to this journal by Dr. Burr Ferguson, medical officer in charge of the United States Public Health Service at Southampton, England, this theory appears to receive confirmation in many respects. Dr. Ferguson has been making investigations in the treatment of certain infections by inducing an increase of white blood cells, or rather he found that in the successful treatment of certain forms of infection in which salicylate of mercury was given the white blood cells were increased very largely. The results accruing from the treatment by Dr. Ferguson appear to show definitely that mercury does not cure the disease, that is, does not act directly upon it, but that its value lies in the stimulation of the production of white blood cells, generally believed to be the main means of defense of the body. The article of Dr. Ferguson favors this theory.

HOMICIDE STATISTICS

Because homicide has become so frequent as to be a menace to insurance companies, and also because of its importance as a social problem, the Metropolitan Life Insurance Company has recently made an investigation of 146 homicide cases taken at random, which in turn led to an inquiry into the procedure of officials and courts in this country. The United States has a homicide rate seventeen times that of England and Wales, and six times that of Canada. Since the investigation showed that only one person out of the 146 paid the death penalty the court procedure inquiry was made, but, the report states, "the exact facts on police and judicial activity for a sufficiently large area of the country are unavailable," so data were secured on the procedure following homicide cases among policy holders. "There have been numerous attempts," the report goes on to say, "to apologize for the extraordinary figures for the United States, but these explanations are highly speculative in character.

The fact remains that in the United States each year many more lives are sacrificed to the homicidal impulse than one would expect from the records of other countries in at least the same advanced state of civilization. It has been hinted that inability to apprehend, indict, and try assailants, and to make prompt and definite disposition of homicide cases were important factors in accounting for the situation in this country. . . . The facts for the 146 homicides show that thirty-two were socalled justifiable homicides! . . . Now what happened to the assailants in the other 114 cases? There was an indictment in sixty-nine cases, or in 60.5 per cent. of the 114 unjustified homicides! The forty-five unindicted cases (39.5 per cent. of the 114 murder and manslaughter cases) showed that in one third the assailants were still at large, that in twenty-two cases the assailant committed suicide, and in eight the evidence was insufficient to warrant indictment.

"What followed the sixty-nine indictments? Eleven were 'no trial' cases! In fifty-eight trials a verdict of 'not guilty' was rendered in sixteen cases, or 27.6 per cent. of the trials. One mistrial resulted. Of the forty-one judged to be guilty, thirty-five are serving time, with appeal pending in six cases; three are being held either for a new trial or pending an appeal; one was paroled, one fined, and one executed! Summarizing: out of 146 homicides, including 114 manslaughter or murder cases, there were thirty-five penitentiary timeservers, one parole, one fine, and one execution!"

Since in 1923 the Metropolitan Life Insurance Company paid out in homicide claims alone $724,000, it feels justified in claiming that "Wholly apart from questions of law, order and safety of the person, this element of American mortality is a source of serious loss to the policy holders of life insurance companies, and from this viewpoint detailed inquiry into origins and remedial action with respect to homicide is warranted."

More serious than this to the average citizen is the meaning of the facts themselves as showing basically wrong social conditions, a failure to handle properly the punitive and prohibitive measures of the country with a view to prevention rather than punishment, and the whole serious problem of the death penalty itself.

Obituary.

JOHN BINGHAM ROBERTS, M.D.

Philadelphia

The death of Dr. John Bingham Roberts, of Philadelphia, on November 28, 1924, means a significant loss to American surgery. Death came as the result of injuries received several weeks ago, when he was struck by an automobile. He was seventy-two years of age.

Dr. Roberts was well known in this country, not only through his success as a practising surgeon, but also for his teaching in various medical schools and colleges, and his writings on his specialty. Among the last were many articles and papers on surgery and medicine, and such well known works as his *Paracentesis of the Pericardium, A Compend of Anatomy, Surgery of the Human Brain, Treatise on Modern Surgery, Modern Medicine and Homeopathy, Fractures of the Radius, Modern Treatment of Fractures,* and *Deformities of the Face.* Dr. Roberts was also a member of the editorial staff of several of the leading journals of medicine and surgery.

He was at the time of his death president of the American Surgical Association, former president of the American College of Surgeons, was president of the American Academy of Medicine in 1904, and president of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania. He held also the positions of professor emeritus of surgery of the Graduate School of Medicine of the University of Pennsylvania, and was professor of surgery at the Philadelphia Polyclinic.

News Items.

Harvey Society Lectures.—Announcement is made of two coming Harvey Society lectures,—January 17, 1925, on "Etiology of Scarlet Fever," by Dr. A. R. Dochez, of Columbia University Medical School, and March 21, 1925, on "Intestinal Absorption of Antigenic Protein in Infancy," by Dr. Oscar M. Schloss, of Cornell University Medical School. The lectures are given at the New York Academy of Medicine.

Samuel D. Gross Prize.—Essays in competition for the Samuel D. Gross Prize will be received until January 1, 1925, by the trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 19 South Twenty-second Street, Philadelphia. The prize is awarded every five years for an original essay on surgical practice or surgical pathology. Details may be obtained from the Academy of Surgery.

Civil Service Examinations.—Examinations for the position of medical intern (psychiatric), entrance salary of $1,860 a year, vacancy at St. Elizabeth's Hospital, Washington, D. C., will be received until June 30, 1925. Examinations for the positions of trained nurse and trained nurse (psychiatric), both male and female, at entrance salaries of from $120 to $140 a month, vacancies in the Panama Canal Service, will be received until January 21, 1925. Applications should be made to the U. S. Civil Service Commission.

Centenary of Charcot.—During the first days of June, 1925, the centenary of the birth of Charcot will be celebrated in Paris, by the Academy of Medicine, the Faculty of Medicine, and the Neurological Society of Paris. Numerous delegates from other countries are expected. At the same time, the Neurological Society of Paris will hold the sixth international reunion, and celebrate its twenty-fifth anniversary. Information may be obtained from Dr. A. Souques, general secretary of the Organization Committee, 17 Rue de l'Université, Paris VII, France.

Reorganization at the Postgraduate.—The New York Postgraduate Medical School and Hospital secured, during the last session of the legislature, an amendment to its charter altering the qualifications for membership in the board of directors. As a result, a reorganization has taken place whereby life membership has given place to membership for terms of six years, and the active attending physicians of the hospital are ineligible for election. There will also be a medical board, consisting of all members of the faculty having professorial rank. This arrangement will free the medical men from the burdens of business management and thus give them more time to devote to scientific work and teaching. The directors are Henry D. Chapin, M.D., Vincent Astor, James C. Brady, Edgar H. Boles, Clarence Dillon, William Fahnestock, William V. Griffin, Ludwig Kast, M.D., James F. McKernon, M.D., George T. Slade and the Rev. Karl Reiland. The officers elected for the ensuing year were: President, Dr. James F. McKernon; first vice-president, William V. Griffin; second vice-president, Edgar H. Boles; treasurer, William Fahnestock, and secretary, Robert E. Allen.

New Fellows of American College of Surgeons.—Lists of fellowships recently conferred by the American College of Surgeons have been announced. These include the following New York and Brooklyn surgeons:

New York: Paul William Aschner, Ernest Archibald Campbell, Mather Cleveland, Harry Cohen, Achilles Edward Davis, Frank Nicholls Dealy, Alexander Duane, Samuel J. Druskin, John H. Dunnington, James Ives Edgerton, Antonio Fanoni, Benjamin Peter Farrell, Harry Finkelstein, Lyon L. Fulkerson, Julius Gottesman, Harbeck Halsted, John M. Hanford, Isaac M. Heller, Russell A. Hibbs, Henry H. Ritter, Solomon Rottenberg, Samuel Jerome Scadron, Emma Selkin-Aronson, Robert J. Shea, William Irving Sirovich, Goodrich Truman Smith, William M. Higgins, Warren Hildreth, Joseph D. Kelly, Arthur Krida, Thomas F. Lancer, Thomas E. Lavell, Maximilian Lewson, Abraham Lightstone, John D. Lucey, Junius H. McHenry, William McLean, John H. Morrissey, William R. Morse, Jos. Augustus Mulholland, Frederick Emil Neef, John M. O'Connor, Salvatore di Palma, Otto C. Pickhardt, Gouverneur M. Phelps, Meyer M. Stark, Maximilian Stern, Alfred H. Thomas, Julius John Valentine, Charles Vejvoda, Allen O. Whipple, August F. A. Wiggers, Arthur S. Wilson.

Brookklyn and Long Island: S. Potter Bartley, Frank Samuel Child, Jr., Burnett Charles Collins, Joseph B. Conolly, Stephen De Coste, William Fawcett-Shaw, George D. Fisher, S. Lloyd Fisher, Arthur Goetsch, George Hills Iler, Robert E. Kinloch, David Livingstone and Harry Meyersburg.

Endowment at Jewish Memorial Hospital.—Beds in both male and female wards at the Jewish Memorial Hospital have been endowed for free treatment of rectal diseases. Dr. Arthur A. Landsman is attending proctologist in charge of the service.

Lecture on Stomatology.—Dr. Anthony Bassler will deliver a lecture on Stomatology in Relation to Internal Medicine at the monthly meeting of the American Stomatological Association, January 8, 1925, at 8.30 p. m., at 50 West Eighty-eighth Street, New York.

Visiting Nurse Service.—The New York Visiting Nurse Service is carrying on a campaign for funds. During the last year 50,300 patients were cared for, of whom 15,727 were children under five years. It is hoped to raise funds for the support of two hundred nurses for the next year.

New Danish Legislation.—A bill has been introduced in the Danish Parliament authorizing the taking of the life of patients "to release a hopelessly ill person from severe and inevitable suffering." Under the old law, this act, at the patient's request, came within the designation of murder or manslaughter.

Pasteur Relics.—Two small flasks and a U-tube, used by Pasteur while dean of the faculty of sciences of the University of Lille, from 1854 to 1857, have been sent to Columbia University by Professor Pascal, of France. The pieces are to be displayed in the Chandler Chemical Museum. Pasteur began his study of fermentation while he was at the University of Lille.

Course in Clinical Stomatology.—Postgraduate courses, open to physicians and dentists, to be held for ten weeks beginning February 18th, are to be given by the New York State Society of the American Stomatological Association, as follows: Stomatological Bacteriology, by William H. Park, M.D., and Charles Krumwiede, M.D.; Physiology of Nutrition and Diet Selection, by Holmes C. Jackson, Ph.D.; and Clinical Stomatology, by Alfred Asgis, D.D.S., John L. Kelly, D.M.D., and N. Philip Norman, M.D. Application should be made to the New York Stomatological Clinics, 33 West Forty-second Street, New York.

Hospital News.—A bequest of one million dollars for the construction of a branch hospital or ward for persons of moderate means has been received by Massachusetts General Hospital through the will of Mary R. Richardson of Newport, Rhode Island.

The Philadelphia General Hospital has opened an annex for women with tuberculosis. The building cost $275,000; the wards contain only from four to eight beds.

The Fifth Avenue Hospital has begun work on a nurses' home.

The James Buchanan Brady Foundation of the New York Hospital, has opened a night clinic for women with diseases of the gallbladder, kidneys, etc.

The Speers Memorial Hospital of Dayton, Kentucky, has opened a new nurses' home, with quarters for thirty-six nurses, as well as classrooms.

The campaign for the Beth Israel Hospital of Newark, New Jersey, shows $1,845,607.20, as the amount raised, over three hundred thousand dollars more than called for.

Personal.—Dr. George Schwartz has been appointed visiting surgeon to the Heckscher Foundation Hospital, of New York.

Edward C. Kendall, Ph.D., of the Mayo Foundation, has been chosen as the Chandler lecturer at Columbia, and he will receive the Chandler medal at a meeting in February.

Dr. Charles Rosenheck has been appointed associate attending neurologist at the Jewish Memorial Hospital of New York.

Dr. Joseph T. Berkowitz, of the staff of St. Mark's Hospital, and Miss Rebecca Garfinkel, of Brooklyn, were married on November 30th.

Dr. Nathaniel Thomas Ennett, of Richmond, Virginia, has been appointed medical director of the city schools.

Dr. W. J. V. Osterhout, professor of botany at Harvard University, has been appointed a member of the scientific staff of the Rockefeller Institute for Medical Research, the appointment to take effect in 1925.

Dr. Emil Altman is the first appointee to the newly created position of Chief Medical Examiner of the Board of Education of New York.

Foreign Correspondence

LONDON LETTER

(*From our own correspondent*)

LONDON, *November 9, 1924.*

PRESIDENTIAL ADDRESS.

Mr. Paterson, a London surgeon who is well known in America, was elected recently to the presidency of the surgical section of the Royal Society of Medicine. On November 5th he delivered his presidential address which he entitled The Lure of the New. With regard to the advances of modern surgery Huxley's cynical remark was quoted that the "Customary fate of new truths is to begin as heresies and end as superstitions" and the speaker went on to point out that nevertheless we are ever seeking new lamps for old. Some of our new lamps have a dazzling brilliance, but their endurance is transient; others shine as beacon lights on the pathway of progress. Although every inventor or originator is not necessarily an Aladdin, he plays a part of supreme importance in surgery. As in every other field of human activity, whether his ideas be trivial or important, he stimulates thought. Like Lister, he may change the whole practice of surgery, or he may merely make some small suggestion which ultimately may prove part of an epochmaking discovery. His new lamps may be useless for the purpose for which they were designed but in other directions may prove of extreme value. Sayre's plaster jacket was intended for the treatment of scoliosis. The method was sound, but its application was erroneous, but by drawing attention to this subject, in time it led to the enunciation of the correct principles on which lateral curvatures should be treated.

The birth of modern intestinal surgery may be attributed to an invention long since discarded, Murphy's button. The introduction of this method demonstrated the possibilities of intestinal anastomosis and by focusing interest on this subject led to methods which have superseded the use of mechanical appliances.

Not seldom the new lamps given to us by inventors are spoilt by injudicious modifications or improper use. When Sir Arbuthnot Lane introduced his method of plating simple fractures, some surgeons employed it for the treatment of compound fractures with unsatisfactory and often disastrous results. They were putting a valuable procedure to a use to which its originator stated it was totally unsuitable. He did not suggest that a new invention cannot be improved, but before attempting to make improvements it is wise to ascertain whether our ideas have already been tried without success. He thought it would be conceded that even the greatest discoveries have disadvantages as well as compensations.

The two greatest blessings given to surgery during the past century, anesthesia and the principles of asepsis, are not excepted from this generalization. Both have tended to prolong operations unnecessarily, so that to this extent they have been harmful although the sum of the benefits they have conferred is priceless. In preanesthetic days the surgeon tried to complete his work as speedily as possible, because he was inflicting pain. With the introduction of anesthesia the surgeon could be more deliberate in his methods and so unconsciously prejudiced the interests of his patients. In this respect the war was a bad training for young surgeons. Many long and very severe operations were performed for abdominal injuries, but the natural resistance of the patients was very different from that of the ordinary patient of civil life.

In his fascinating presidential address to this section two years ago, Mr. James Berry emphasized the value to the young surgeon of a thorough training in the making of postmortem examinations. He would add to this wise advice that, in addition, some experience as an anesthetist should form part of the training of anyone who aspired to practise surgery. He would learn not only many useful surgical lessons, but he would understand more of the shock produced by operations. The drugs used to induce anesthesia are highly toxic, and we are apt to forget that apart altogether from the effect of the operation, the anesthetic has also a harmful influence on the patient. Every experienced anesthetist knows that even the strongest patient begins to flag perceptibly after an hour, and after an hour and a half this change is yet more accentuated. Dr. R. T. Morris of New York relates how a house surgeon, who had served under two surgeons of about equal capability, was asked his reason for the difference in their statistics. His reply was "About ten minutes." There was a wealth of wisdom in this seeming exaggeration. The expert anesthetist not being a politician keeps our patients in such a state of tranquillity that we are tempted to be almost too deliberate, and to forget the importance of rapid, or rather expeditious operating. We must not make a goddess of technic and to forget it is of no less importance to assist nature by conserving the patient's resistance. Better incomplete technic and a live patient than a perfect technic and a dead patient.

He was not sure that a good case could not be made against the use of rubber gloves. At any rate, Sir Harold Stiles without them has achieved results surpassed by none. Lawson Tait, too, showed what could be done with a simple technic and expeditious operating. His results were so good that the surgeons of his day took refuge in regarding their accuracy with an attitude of unphilosophical doubt.

Not the least interesting part of the address was that in which intestinal stasis and its aftereffects were dealt with. This subject was thus commented on. Not one of the least dazzling lamps given to medicine in recent years is the hypothesis that intestinal stasis is responsible for many of the ills to which our flesh is heir. It is alluring in its simplicity and fascinating from the vista of hope which it opens up. It has been given to few to originate two such startling proposals as the operative treatment of simple fractures and the surgical treatment of intestinal stasis and Arbuthnot Lane has not escaped

the criticism and bitter opposition which falls to the lot of all pioneers. Few subjects have excited greater controversy than the statement that intestinal stasis produces toxemia. It has been assumed that such teaching is unscientific, because we do not know the nature of the toxins produced or even of their existence. The argument need not perturb the seeker after truth. The malaise and debility which accompany tuberculosis were recognized long before the discovery of the bacillus which cause the constitutional symptoms. This much at least we do know, that patients who are the victims of a disorder which impairs their mental and bodily vigor, which causes such constant discomfort and pain as to reduce them to a state of misery, and which renders them incapable either of work or enjoyment of the pleasures of life, may be relieved by treatment directed to the removal of existing intestinal stasis. This is a truth established by the work of surgeons all the world over. When, however, we consider to what extent surgery should interfere there is room for wide divergence of view. Whether all Lane's teaching be true or not, time alone can show, but without doubt the lamp has cast light in hitherto dark places, and has led to a new conception of abdominal disease.

The speaker then took a tilt against the extent to which specialization has been carried nowadays. He likewise saw reason to regret the reliance or rather dependence placed on the laboratory for diagnostic purposes, and deplored the manner in which clinical observations and methods were comparatively neglected, almost falling into disrepute. He thought this tendency was to be greatly deprecated. He pointed out that the surgeon of the day was not a carpenter to operate at the behest of others, but rightly expected to make his own diagnosis and form his own judgment. Indeed, according to Mr. Paterson a surgeon may be defined as a physician who has learned to use his hands.

Sir St. Clair Thomson, the president of the Royal Society of Medicine, in moving a vote of thanks to Mr. Paterson for his address, made some of those witty remarks for which he is famous. In referring to Mr. Paterson's definition of a surgeon as a physician who has learned to use his hands, he said that the retort to this was obvious and as he was a fellow of the College of Physicians as well as of the College of Surgeons no one was better fitted to make it than himself. The physician was the surgeon who had learned to use his brains.

APPOINTMENT OF DR. LLEWELLYN J. LLEWELLYN AS A MEMBER OF THE BOARD OF MEDICINE FOR THE UNIVERSITIES OF WALES

There exists a great desire among those who have the welfare of Wales and of the Welsh medical schools at heart to unite the Welsh medical schools into a Welsh national medical school of2 medicine. Dr. L. J. Llewellyn, who has been appointed recently a member of the Board of Medicine for the Universities of Wales, is peculiarly well fitted to lend substantial aid to develop the embryo scheme and to bring it to completion. He enjoys an international reputation as an authority on gout, fibrositis and diseases which are generally, although perhaps incorrectly, classed under the head of rheumatism. Dr. Llewellyn has written a classic on gout, which has been translated into French at the express wish of French experts on the subject. He has also written a classic on fibrositis and masterly works on some other phases of rheumatism. He served on the Pensions Board during the war and wrote a much quoted book on malingering.

The catholic outlook necessarily implanted and engendered by these various activities have given Dr. Llewellyn not only a medical but medicolegal outlook which will undoubtedly make his assistance in drawing up and carrying into effect a plan for the amalgamation of the medical schools of the Welsh Universities into a national school, of the utmost value. It should be added that the scheme is still quite subjudice and that there are many difficulties to be encountered and overcome ere success is even in sight. However, as said before, the scheme is good and one which will commend itself to all patriotic Welshmen, of whom Dr. Llewellyn is by no means the least patriotic, wherever they may dwell.

GENEVA LETTER

(*From our own correspondent.*)

GENEVA, *November 17, 1924.*

SWISS SOCIETY OF PSYCHIATRY

The program of the Swiss Society of Psychiatry, which met at Zurich on November 15th and 16th was devoted to the subject of general paralysis and on account of the importance of this question of mental pathology the titles of the reports and papers read are highly interesting. The first report, by Professor Binswanger, of Kreuzlingen, was on the pathology and pathogenesis of general paralysis, and this was followed by a paper by Professor Maier, of Zurich, on the statistics of general paralysis in the Swiss asylums. Dr. Steck, of Cery, read a paper on the striate syndrome of general paralysis, while Dr. E. Minkowski, of Paris, presented a remarkable paper on the comparative psychology of general paralysis and schizophrenia.

After a discussion of these papers Professor Spielmeyer, of Munich, read a report on the pathological anatomy of general paralysis, and Dr. Steck, of Cery, gave an interesting demonstration of neurological proliferations in this disease. Dr. Targowla, of Paris, treated the subject of serology in general paralysis, these contributions being followed by the report read by Professor Hoche, of Freiburg in Brisgau, on the treatment of this disease. This unusually successful meeting closed with two interesting contributions, the first by Dr. Bersot, of Zurich, on malariatherapy of general paralysis, the second by Dr. Brunner, of Küssnacht, on the endolumbar treatment of general paralysis, according to Gennerrich's method.

PASTEUR INSTITUTE REPORT

From the report of the Pasteur Institute at Bern, of the work accomplished during the year 1923, it appears that seventeen persons received prophylactic treatment for rabies. For so small a population as Switzerland, these figures may appear relatively large, and when compared with the number treated

in 1921 (twelve) and four in 1922. The canton of Tessin sent twelve cases, the cantons of Bern, Lucerne, Vaud and Neuchâtel respectively two, one, one, one.

Of the patients treated, twelve—being all those from the Tessin—had been bitten by animals with avowed rabies; in the remaining five the animals were under suspicion. In sixteen cases the animals were dogs, while the seventeenth patient was bitten by a fox who attacked the child while at play. Autopsy of the fox showed that the animal was not rabid. All the patients remained well after treatment.

NEW EDITION OF THE PHARMACOPŒIA HELVETICA

The committee ordered to prepare a new edition of the Pharmacopœia Helvetica has nearly completed its work and the new edition will be published shortly which, if it is as concise and simple as the present one, should be a model for all countries.

INTERNATIONAL OPIUM CONVENTION

The International Opium Convention will have completed its work by the end of this year. I learn from a competent source that the Swiss Government intends to ratify this international act without delay. Besides, in conformity with the practice adopted and according to which all ratifications of international conventions must be accompanied by legislative acts destined to assure their application. The Federal Council will submit to the Federal Assembly a draft of a law regulating the sale of narcotics and stupefacient medication following the general stipulations of the opium convention.

SMALLPOX IN SWITZERLAND

The smallpox epidemic in Switzerland, which commenced in 1921, still exists and shows a distinct tendency to spread. In point of fact there are now sixteen cantons invaded, as against thirteen in 1922. In some the disease is merely sporadic. Last year the total number of cases reported was 2145, as against 1159 in 1922. Of the 2145 cases, 1315—or more than 50 per cent—were reported from the canton of Bern, this being the most important focus of the disease. After Bern, the most infected cantons are Zurich, Lucerne, Argovie and Thurgovie.

The epidemic has maintained a relative benignancy from the onset since only one death has been recorded, that of a sixty-nine year old man. This benign character seems to apply to all present smallpox epidemics, particularly England, and this fact is interesting because it would seem to show that we are not dealing with an accidental phenomenon, but with a more general one, conditioned by a time attenuation of the virus, the cause of which is as yet not clear.

Although the mortality has been practically *nil* in Switzerland, it must be pointed out that many of the cases were serious forms of the disease and there is nothing that can lead one to suppose that at any time the disease may not suddenly assume its usual virulence, as is the case with other transmissible diseases.

The Swiss authorities are dealing severely with the epidemic and the value of compulsory vaccination has given ample proof of its real value. In the cantons of Tessin and the Grisons, where the law is conscientiously applied, not a single case has developed, and this likewise applies to French Switzerland —Geneva, Lausanne, etc.—where the law of compulsory vaccination is in force.

SANITARY CONDITIONS IN ORIENTAL EUROPE

At the present writing the sanitary condition of Oriental Europe—especially Russia and Poland—has notably improved and has relieved certain fears of the Swiss sanitary authorities which last year were entertained for very good reasons. This improvement is unquestionably in part due to the activities of organizations created by the League of Nations. These are under the direction of highly competent personalities and the results obtained have been truly remarkable. The epidemics of typhus, cholera and the plague, which were a menace to all Europe, have progressively been repelled; their foci have been narrowly walled off, thus diminishing the areas of disease. It should be said that the Swiss quarantine stations at the frontier, existing at Bâle, Buchs, Chiasso and Brigue, have been admirably organized and have controlled the sanitary condition of 21,014 travelers who entered Switzerland, 19,510 coming from countries where typhus existed, while 1,504 came from countries where the plague raged.

LATIN AMERICA LETTER

(From our own correspondent.)

Balboa Heights, Canal Zone,
November 14, 1924.

AMERICAN PHYSICIAN HONORED BY CHILE

Upon the reorganization of the new government of Chile, the new President of the Republic cabled the Chilean Ambassador at Washington, instructing him to negotiate for the services of Assistant Surgeon General John D. Long of the United States Public Health Service to serve as director of the newly organized Department of Health of Chile. Doctor Washington. In the course of his official work he has spent many years in the Philippine Islands where he was first chief quarantine officer and later chief health officer. At present he is chief of foreign and insular quarantine of the U. S. Public Health Service, and medical director of the Pan-American Union at Washington. In the course of his official work he has made many trips to Central and South America for the purpose of studying various health conditions in these countries. He speaks Spanish fluently and has made many sincere friends among the officials of Latin America. At the time of this writing it has not been learned whether or not Dr. Long has accepted the invitation to go to Chile, but that country will be extremely fortunate if it succeeds in securing the services of this able sanitarian.

COSTA RICA ESTABLISHES SCHOOLS FOR SANITARIANS

At the last session of the Costa Rica Congress, a bill was passed by that body and signed by the President authorizing the establishment of a School of Public Health for Sanitarians. This school will be run in conjunction with the Public Health Laboratory recently established through funds donated by the Rockefeller Foundation. Graduates will be given employment by the Government to promote health

work throughout the Republic. The Government has also recently established a Division of Vital Statistics in its Department of Health. In this connection, Dr. José Guerrero has been sent to Johns Hopkins University to study under Professor Pearl. Upon completing his course Dr. Guerrero will return and take charge of the Division of Vital Statistics.

FLU-LIKE EPIDEMIC AT THE CANAL ZONE

Colonel W. P. Chamberlain, Chief Health Officer of the Panama Canal, announces the appearance of an epidemic, flu-like in character, but milder than the previous epidemics. More people have been affected upon the Pacific than the Atlantic side of the Isthmus. Adults and children have been affected alike and during the second week in November there were 156 children out of school. While the symptoms are somewhat mild, the disease has confined most of its victims to bed for four or five days with a slight fever. The eyes have been greatly affected both with severe pain and photophobia. A harsh bronchial cough lasts for several days and does not seem to respond to medication.

SCIENTIFIC EXPEDITION VISITS CANAL

His Majesty's steam yacht, *St. George* of the British Royal Yacht Club, tied up a few weeks ago at the Balboa docks of the Canal. The ship is bearing a body of British scientists to islands in the Pacific Ocean, where they will study and secure specimens of all forms of nature. The expedition is in charge of Captain Blair, retired commander of the British Navy. The complement includes scientists versed in biology, geology, climatology, medicine, etc. An author and a marine artist are in the group which includes also a cinematographer who will take pictures of animal and bird life of the islands. During the month of June the *St. George* first transited the Canal, on its way from England to the Galapagos Islands, where a very successful stay was made studying the reptile and animal life of these interesting islands. Upon leaving the Canal, the yacht will make a five months' tour of the Marquesas and other little known islands of the Pacific Ocean.

ISTHMIAN CANAL ZONE MEDICAL ASSOCIATION MEETING

The 214th meeting of the Isthmian Canal Zone Medical Association was held at the Colon Hospital on the Atlantic side, Tuesday, October 28th, at 8 p. m. As a rule these meetings are held at the Ancon Hospital on the Pacific side, but out of courtesy to the Atlantic side physicians, the meeting was this time held in Colon.

The following interesting program was presented by the staff of the hospital: 1. Report of a Case of Multiple Lacerated Wounds Resulting from Attack by a Barracuda. 2. Report of a Case of Perthes Disease with Discussion of This and Allied Bone Conditions, by Major T. S. Mebane; discussion opened by Dr. R. W. Runyan. 3. Report of a Case of Ulcerative Endocarditis, by Dr. W. F. Hamilton; discussion opened by Lieut. Colonel Roger Brooke. 4. Preliminary Report of Four Cases of Chronic Gonorrhea Treated with Muecurchrome, by Captain Frank Romaine; discussion opened by Dr. C. Holmes. 5. Report of the delegates to the meeting of the American Medical Association.

The most interesting report of the evening was that of the barracuda bite. A brief history of the case is as follows: An enlisted man, about twenty-six years of age, was swimming 200 yards off shore in the Atlantic Ocean when he was suddenly attacked by a large fish. During the struggle a greater part of the muscles of the calf of his leg were torn away and numerous lacerations made in the thigh. Through almost superhuman strength the man was able to free himself from the attacks of the fish and was finally rescued by two companions in a boat. Several bloodvessels had been cut and when rescued the man was in a state of collapse due to loss of blood. A tourniquet was applied to stop hemorrhage and the man was rushed to the hospital. He was immediately operated upon and made a slow but uneventful recovery. Even with the loss of a great deal of muscle structure the leg now functions well and the man has been returned to active duty. This case illustrates the ever present danger of swimming far out in tropical waters, where sharks and other large fish abound. Such attacks on human beings are not common in the water adjacent to Panama. Barracudas and sharks abound and many people go in swimming, yet in seven years only three other instances of similar attacks have come under the observation of the Canal Zone hospital authorities. Two of these attacks were made by alligators and the third by a shark.

GORGAS DAY IN THE CANAL ZONE

The following announcement has been made by Colonel M. L. Walker, Governor of the Pamana Canal:

A movement is now under way to establish and maintain a research laboratory on the Isthmus as a permanent tribute to the memory of Doctor William Crawford Gorgas. The laboratory, which will be managed by leaders of medical science, will be used for research work in the prevention of disease.

Doctor Gorgas' achievements in the cause of disease eradication are too well known here to require recounting, except to say that the sanitary measures advocated and enforced by him contributed largely to the successful completion of the Panama Canal. No more appropriate tribute could be rendered to the memory of this great man of science than that of perpetuating his memory and ideals in an institution dedicated to the great work on which he was engaged.

A campaign, which has the hearty endorsement of the Canal Zone Government, is being conducted to raise funds necessary for the purpose. It seems fitting therefore that a special day should be named on which the health principles advocated by Doctor Gorgas may be given the serious consideration which they deserve.

Accordingly, Sunday, November 16, 1924, is announced as Gorgas Day. All are asked to cooperate in giving emphasis on that day, by whatever means may be available, to the relation between health and good citizenship, and to the vital importance of continuing the researches of medical science in the hope that at some not far distant day the ravages of disease in the world may be conquered.

SANTO TOMAS HOSPITAL SUPERINTENDENT RESIGNS

On account of official order from the Secretary of War, Major Edgar A. Bocock, Medical Corps, U. S. A., has resigned as head of the Santo Tomas Hospital, Panama, and has left for the United States, where he is assigned to duty. Under a new arrangement, a Panaman physician has been appointed superintendent by the President of Panama.

Book Reviews

PEDIATRICS

Pediatrics. By Various Authors. Edited by Isaac A. Abt, M.D., Chicago. Volume IV, with 218 Illustrations. Philadelphia and London: W. B. Saunders Company, 1924. Pp. xii-1271.

This volume includes chapters on diseases of the thoracic organs, surgery of the thorax, the physiology of the circulation, diseases of the heart, bloodvessels and the blood, an exhaustive study of electrocardiography, the transfusion of blood, diseases of the endocrine glands, and diseases of the lymph nodes, each of which is discussed by an authority on the subject. The last word on the subject of endocrinology may be found here. Much space is devoted to discussion of diseases and conditions of the urinary tract. The male and female genital organs and their diseases in childhood are discussed in detail.

The bibliography is extensive, but it is unfortunate that some of the more recent literature is not cited, which is an inherent fault of all large systems of medicine. The historical aspect of medicine is given ample consideration. The physiological aspect of the study of disease is discussed in detail and applied to the diseases of childhood. The entire volume presents an exhaustive study of the subjects treated. It is an addition of distinct value to the department of pediatrics.

DISEASES OF CHILDREN

Lehrbuch der Kinderheilkunde für Arzte und Studierende. Von. Dr. med. Bernhard Bendix, a. d. Achte Auflage, mit 93 Abbildungen im Texte und 7 Farbigen Tafeln. Berlin und Wien: Urban & Schwarzenberg, 1923. Pp. xii-639.

In order to make this, the eighth revised edition of this book, of the most practical value to medical students and practitioners of medicine, special emphasis is laid upon the clinical aspects of pediatrics and therapy. It has been translated into the Italian, Russian, and Spanish languages. Pathology in pediatrics has been left in the background. The introductory chapter deals with the development and hygiene of the healthy infant and child and the treatment of the sick child in general. The most important diseases of the newborn are treated in a separate chapter. General diseases, including diseases of the blood and hematopoietic organs, the hemorrhagic diathesis, constitutional anomalies, and diseases of metabolism are taken up in one chapter. The chapter on the diseases of the digestive organs, including the various forms of malnutrition is replete with practical suggestions of a dietetic nature: detailed instruction is given regarding the different forms of artificial feeding. However, the subject of vitamines, which promises to play a very important part in the future, is not given sufficient attention. The diseases of the respiratory and circulatory systems, respectively, are also discussed. The diseases of the urogenital apparatus and of the nervous system are taken up in greater detail than is usual in textbooks on pediatrics. The infectious diseases and the diseases of the skin are also discussed in great detail. The bibliography is extensive but not complete or up to date, as much of the more recent and important literature is omitted and there are few references to authors other than German.

RADIOTHERAPY IN CHILDREN'S DISEASES

Strahlenbehandlung bei Kinderkrankheiten. Von Prof. Dr. W. Birk, und Dr. L. Schall. Mit 13 Figuren im Text und auf 2 Tafeln. Berlin, Wien: Urban & Schwarzenberg, 1924. Pp. vi-77.

This monograph is presented as the first on the subject of ultraviolet (quartz lamp) therapy and röntgenotherapy as applied in the diseases of children. Not only is the technic of irradiation described in detail, but also the clinical reasons for the treatment, as the authors determined them in their observations and experiments over a period of many years.

The first part deals with the application of quartz lamp therapy in rachitis, spasmophilia, the various forms of tuberculosis in children, and also in other diseases of children, such as erysipelas, pertussis, varicella, chronic infiltrating eczema, bronchial asthma and in enuresis nocturna.

The second part is devoted to röntgenotherapy and includes the technic of the treatment of the various types of tuberculosis occurring in children, of endocrine disturbances (thymus, thyroid, hypophysis and suprarenal glands), of the blood and hematopoietic organs (leucemias, pseudoleucemias, splenomegalies and the hemorrhagic diathesis), and of the exudative diathesis (chronic eczema, bronchial asthma and hypertrophy of the pharyngeal lymphatic ring). The final chapter deals with the röntgen ray injuries.

BOOK FOR YOUNG MOTHERS

The Happy Baby. Editorial Adviser: L. Emmet Holt, M.D. New York: Dodd, Mead & Company, 1924. Pp. 120.

"We can have better health for ourselves and our children if we will. Physicians who are interested in this campaign for saving child life and improving child health believe the greatest weapon against disease is not medicine but knowledge—accurate, definite knowledge applied with common sense." In these words Dr. Holt in the introduction to this little book for mothers, particularly those who are mothers for the first time, summarizes his purpose in writing and editing it. He himself is the writer of several of the chapters on general and special problems of infant care, and other sections are included. Harvey J. Burkhart, Ralph Lobenstine, and Henry L. K. Shaw. The articles are among those originally published in the Happy Child Department of the *Delineator*, for which Dr. Holt was for some time the editorial adviser. Among the chapter headings are the General Care of the Baby, Care of the Expectant Mother and the New Baby, Maternal Nursing, Artificial Feeding, Diet Problems of Childhood, Early Childhood, The Child's Teeth. These various topics are treated in simple, nontechnical language, so that even the mothers with little or no education may grasp them easily. Discussions and advice as to

psychological as well as physical states and symptoms of both mother and child are included, necessary supplies are listed, food formulas are tabulated, and many other practical hints and suggestions are given which are too often omitted in similar works.

INFANT FEEDING

Physiopathologie de L'Appareil Digestif du Nourrisson. Par Enrique Suner. Préface du Dr. Nobécourt. Traduction du Dr. Mathé. Paris: Masson et Cie, 1924. Pp. 89.

This pamphlet of ninety pages by Dr. Enrique Suner, professor of pediatrics at the University of Madrid, is translated into French by Dr. Mathé. Beginning with a discussion of digestion in general, there are taken up in order such topics as the influence of bacteria on intestinal digestion, the transformation of the principal foodstuffs, the composition of the protein molecule, energy requirements in the nursling, calorimetry, individualization in artificial feeding, milk dilution, supplementary feeding, determination of calorimetric values by simple rules, the Pirquet system, etc.

On the whole the little book presents a serviceable review of our present day knowledge of infant feeding.

DISEASES OF CHILDHOOD

Säuglingsheilkunde der täglischen Praxis. (Mit einzelnen Hinweisen auf das spätere Kindesalter). Von Prof. Dr. K. Blühdorn, Göttingen. Berlin, Wien: Urban & Schwarzenberg, 1924. Pp. viii-190.

Clinique Médicale des Enfants. Affections de L'Appareil Respiratoire. By P. Nobécourt. Paris: Masson et Cie., 1924. Pp. 348.

Blühdorn's handbook consists of a number of articles on pediatric subjects with reference to the disease of childhood, formerly published in the *Medizinische Klinik,* but which are now published in an amplified form. It is intended for daily use by the practitioner and student and the subjects are treated in a practical manner. Theory is mentioned when it is applicable in practice. The arrangement of the material is rather desultory and follows the principle of utility in differential diagnosis. Only the most important features are discussed in detail, but nothing of practical importance and of specific application in infancy is omitted.

* * *

The respiratory system of infancy is dealt with by P. Nobécourt in this, the first volume of several publications which will appear in a series. As the title indicates, the book treats of the diseases of the respiratory system in children. It gives the history, the method of examination, diagnosis, differential diagnosis, and the treatment. The subjects are taken up in detail and the book will be helpful to student and practitioner alike. It will be of assistance in avoiding the mistakes so often made because the little patient is unable to designate localization of pain, or discomfort, and the symptoms and signs are too often indefinite.

Not only the general practitioner but the specialist also will find valuable hints in this interesting volume and the reviewer expresses the hope that some of our eminent American specialists in diseases of children will find it worth while to translate this work by Prof. Nobécourt.

AN ATLAS OF SKIN DISEASES

Atlas und Grundriss der Hautkrankheiten. Fünfte, teilweise umgearbeitete und erwiterte Auflage. Von A. Jesionek und Dr. Mravek. Herausgegeben von Dr. med. Paul Mulzer. Mit 109 farbigen Abbildungen auf 52 Tafeln und 85 Textbildern. Lehmann's Medizinsche Atlanten, Band XV. München: J. F. Lehmann's Verlag, 1924.

This volume is one of the series of medical atlases published by Lehmann. It consists of 254 pages, including text and illustrations. The text is the work of three writers who are responsible for the successive editions. As the basis of this is from the pen of the late Professor Mracek it is excellent and authoritative. As the volume is principally classed as an atlas its value must be largely judged by the quality of the illustrations. The latter consist of fifty-two plates containing one hundred and nine colored illustrations and in addition eighty-five black and white photographs scattered through the text. Of the colored plates some are reproduced from wax models and others from oil paintings or water colors. A few of them are excellent, some fairly good and others are so poor that a proper diagnosis could not be made by the most expert dermatologist. There is no excuse for making illustrations at the present date from paintings when much more accurate reproductions can be made from photographs or wax models. The black and white illustrations from photographs, while not of very high quality, are fairly good. The volume is of little value to the specialist and as an atlas is not worthy of recommendation to the general practitioner.

ANGINA

Angina Pectoris. By Sir James Mackenzie, M.D., F.R.S., F.R.C.P. Oxford Medical Publication. London: Henry Frowde and Hodder and Stoughton, 1924. Pp. 253.

The views of Sir James Mackenzie on angina pectoris are well known and in this book he presents them with force and clarity. Whether or not one agrees with him, one cannot read the volume without gaining much food for reflection, as well as intellectual stimulation, from his careful clinical observations and lucid thought. Mackenzie's thesis is that angina pectoris is a symptom caused by exhaustion of the heart muscle, which is experienced to a different degree by different individuals depending on the sensitiveness of their nervous systems. The same mechanism is believed to explain all heart pain —there is no pain peculiar to angina—but the significance of the pain is determined by the circumstances under which it arises. His approach to the problem is through a study of pain and its physiological mechanism. He first presents his well known studies on referred pain and discusses their application to the subject in hand. He points out that visceral pain is produced by the contraction of muscle, particularly of smooth muscle; and while he concedes that heart pain cannot be produced by a "spasm of the heart," he believes that the cardiac muscle can produce pain when it is confronted with work greater than it can readily overcome, and that this pain arises through a summation of stimuli. He recalls that voluntary muscle, forced to contract when its blood supply is deficient, gives rise to pain, and by analogy explains the pain of angina pectoris as due to contraction of the heart muscle under an inadequate

blood supply. This would explan the association of coronary artery disease with angina pectoris as well as the fact that the pain usually comes on after effort. Other causes of exhaustion of the heart may, however, be at fault. Secondary angina pectoris is explained by a hypersensitive nervous system in which a weak stimulus, which, in a normal person, would be unperceived, such as, for instance, the natural increase in strength and rate of the heart beat after exercise, gives rise to sensations similar to those following severe cardiac exhaustion in non-sensitive individuals. In other words, pain and the associated symptoms depend on, 1, the strength of the stimulus, 2, the susceptibility of the nervous system. Fundamentally Mackenzie's point of view is as follows: Angina pectoris is a symptom of heart failure. "The symptoms of heart failure are produced in two ways, first, by the organs, which receive an insufficient amount of blood, secondly, by the exhaustion of the heart muscle. In the second of these ways the heart muscle gives rise to the symptoms and they are not shown by the heart, but are made manifest through the intervention of the nervous system, giving rise to pain in varying degrees and other signs of nerve stimulation, such as those that are included under the term angina pectoris." An interesting and instructive series of 160 case records are appended to the text. Every clinician will benefit by a careful study of the book.

PATHOLOGY

Pathological Technique. A Practical Manual for Workers in Pathological Histology and Bacteriology, Including Directions for the Performance of Autopsies and for Clinical Diagnosis by Laboratory Methods. By Frank B. Mallory, M.D., and James B. Wright, M.D. Eighth Edition, revised and enlarged. With 180 illustrations. Philadelphia and London: W. B. Saunders Co., 1924. Pp. 666.

Since its first appearance, nearly thirty years ago, this work has been standard. Its popularity will be enhanced by the present edition. Originally designed especially for practical use in pathological laboratories, both as a guide to beginners and as a source of reference to the advanced, it more than fulfills its promise. There has been a thorough revision of the sections and chapters devoted to bacteriology, serum diagnosis, the blood, examination of the spinal fluid. Other sections which have been rewritten include the essentials of photomicrography, pigments, fats, and lipoids, and museum preparations. A valuable feature to this reviewer is the introductory table of contents which allows a clear survey of the work as well as reference to any desired topic.

OTOLARYNGOLOGY

Clinic et Iconographie Medico-Chirurgicales des Maladies de la Face et du Cou. Par Henri Aboulker. Preface du Professeur Pierre Sebileau. 420 Photogravures. Deuxieme Edition. Paris: A Maloine et Fils, 1924.

This is the second edition of an interesting collection of clinical cases by a man who has evidently had an extensive experience in the surgery of the ear, nose and throat and adjacent regions. The method of exposition is essentially practical, devoid of dogmatism. The aim is to have the reader follow the author through the history, symptomatology and treatment of the case. The field covered by the author is wide, from the extraction of foreign bodies from the external auditory canal to major operations on the brain. What may be of special interest to the American reader is the author's warm advocacy of local (infiltration) anesthesia as a method of choice in every case. The clinical portion of the book is supplemented by a remarkable collection of over four hundred photographs of diseases of the ear, nose and throat. Unfortunately many of them are poorly executed.

The otolaryngologist reading French will find this collection of clinical cases of great interest, both from the variety of pathological conditions presented, and the vigorous and convincing style with which they are discussed.

LEUCOCYTIC FERMENTS

Les Ferments des Leucocytes en Physiologie, Pathologie et Thérapeutique Générales. Noël Fiessinger. Paris: Masson et Cie., 1923.

This is an admirable summary of all that we know about leucocytic ferments. As the author himself has contributed a great deal to the subject, he writes of it with an intimate knowledge. The book should be translated, so that it will be available to those who are not familiar with French.

MEMOIRS

Besonnte Ergangenheit. By Dr. Karl Ludwig Schleich. Berlin: Ernst Rowohlt, 1923.

Karl Ludwig Schleich, who introduced into medical science in 1894 infiltration anesthesia, has recently published his memoirs; but, although Schleich is one of the most famous German surgeons of his day, these memoirs deal chiefly with the interests and ambitions of the artist whom the author in his youth wished to become. He is also a poet of no small ability, as his recently published poems reveal. He considered for a time becoming an operatic singer for he had a good voice, a pleasing personality and considerable talent as an actor.

His book, however, touches upon many subjects and incidents of interest to medical literature. He believes that the idea of his method of local anesthesia came to him as a direct "inspiration"; he had his first clue to the idea during a conversation with the famous young Polish pianist and psychologist, Stanislas Przybzsewski, whose mysterious disappearance has never been solved. They were discussing methods of softening the notes from piano strings, and later investigations along these lines resulted in the perfection of his method of anesthesia. It was ten long years, however, before the virtue of this was acknowledged by the profession. Schleich's closest friends in his youth were August Strindberg and Richard Dehmel. He tells us of the former's investigations into the nervous systems of plants, and of his discoveries relating to the functions of the ganglia cells of plants, subsequently confirmed by the studies of the great botanist, Reinke. He tells us that Strinberg made also many experiments in alchemy, and succeeded, in his search for gold, in producing a metal which the scientists of the day were unable to analyze.

It is to be hoped that an English translation of this interesting and important work will soon be forthcoming.

PSYCHOLOGICAL STUDIES

Taking the Literary Pulse. Psychological Studies of Life and Letters. By Joseph Collins. New York: George H. Doran Company, 1924. Pp. 317.

One can make a wide acquaintance with many writers through Collins's studies. It is a disappointing acquaintance, however, in many respects. One looks, in the first place, for more profoundly enlightening psychological meanings to the works discussed than Collins takes the trouble to give. True and deep analyses of characters and situations, or what they represent in the personalities of their creators, are not given. There is scoffing criticism, not infrequently, of the psychology, chiefly the Freudian, which it is assumed the author is trying to represent. There is no deep search for the actual pulse beat of the human conflicts which seek means of expression. One cannot help feeling that Collins has missed an opportunity to stir his readers to thought upon the great psychic unrest which underlies the vast output of literature. As it is, the book deals with this so superficially that its psychology does not justify the wide range of often mediocre literary material set forth.

CARE OF THE HEART

How Is Your Heart? Intimate Talks on the Prevention of Heart Disease and on the Care of an Already Damaged Heart. By S. Calvin Smith, M.S., M.D. New York: Boni and Liveright, 1924. Pp. 208.

This book by Dr. Smith is designed for the laity, in particular for individuals suffering from heart disease. Written in a breezy, colloquial style, and withal with accuracy and clarity, it should find a wide circle of readers. The last three chapters covering "How to live when damage is already done," "Appropriate exercise for heart patients" and "Appropriate occupations for heart patients" are particularly good.

The physician can well recommend the book to his patients; but in the opinion of the reviewer, he would be wise to caution the reader that Dr. Smith's views on the importance of focal infections in the development of heart disease, in particular on the great peril that he believes may lurk in the teeth and tonsils, are unduly magnified.

On page 69 the author, by a slip of the pen, speaks of typhoid antitoxin instead of vaccine.

SCIENCE OF THE FUTURE

Dædalus or Science and the Future. A Paper Read to the Heretics, Cambridge on February 4th, 1923. By J. B. S. Haldane. Today and Tomorrow Series. New York: E. P. Dutton & Company. 1924. Pp. v, 93.

Haldane speaks to minds already heretic or to those afraid to venture into courageous thought of the future. He stimulates his readers to face appalling facts of danger inherent in the science of the present and the possibilities—scarcely less appalling because of their newness and their daring—with which he looks into a course of constructive activity for the generations to come. As the author points these out, they lie in territories, they belong to conceptions that exceed the accepted limits of the conventional thought of the day. They demand reversal of æsthetic, yes, even moral, appreciation. Yet such change, we are reminded, has taken place before even in those greater matters which now lie as the bedrock of our social customs. These became accepted so long before the present era of civilized humanity that things which could be found offensive in themselves have long been quite otherwise regarded. The basis of our advance, through the practical measures which this broad visioned scientist foresees, or through the intellectual and æsthetic life which will accompany these, is a reëducation; an appreciation of what the medium of future culture is to be. Science, especially the wonder world of biology, scarcely yet touched, is to be the material of artist and poet. In science lies the menace to civilization; in science therefore must be its next sphere of salvation.

REVOLUTION

A Week. By Iury Libedinsky. Translated by Arthur Ransome. New York: B. W. Huebsch, 1923.

Wine of Fury. By Leigh Rogers. New York: Alfred A. Knopf, 1924.

An Outlaw's Diary. By Cécile Tormay. Vol. I, Revolution; Vol. II, The Commune. New York: Robert M. McBride and Company, 1924.

The literature of revolution is being written. Already a novel of New Russia has struck a note of understanding the world over. In his great book of slim proportions, *A Week*, Libedinsky has chosen for the universal crisis just one short week in an outlying town of Russia. The contacts with current events that each one of the characters has, furnishes all that is necessary of the past. The assortment of types and beliefs to be found everywhere, are seemingly picked out at random here. The gigantic clash between the old and the new, the ramifications of Soviet government, the steady ununderstanding opposition, and the dogged pursuit of an ideal that inspires every worker for the new beliefs, are thrown into dramatic relief against this background of everyday life in the provinces. In the fewest words, without adornment, nothing but pure elements, Libedinsky creates an enduring, pulsing week that sears memory without destroying hope.

* * *

In Petrograd the tale of the revolution follows more conventional models in an interesting novel, Leigh Rogers's *Wine of Fury*. Especially is the effect upon a disinterested spectator emphasized. An American bank manager with the slightest knowledge of the purposes and thought of the vast country into which he is thrown, still in the turmoil of the revolution, applies American made ideas and ideals. He wades through gore, as it were, with always his own goal only in sight. He loves a Russian girl; his emotions are constantly within a fraction of plunging him unresisting into the whirlpool that seethes about him, and yet he continues through his days and nights, scarcely aware of how close he is to the brink. The American consciousness settles over him. Maybe it ruins his life—his real life. His business life it assures.

The picture of the revolution is frightful and realistic. No one has the right to say whether it is overdrawn. We have too much of David Rand's "American consciousness" to be willing to accept unquestioningly the things that are there and that do not even bear their full import to *his* mind. Rogers has given us a history of fact, a dramatic

conflict of emotion, a solution that, like life or death, is no solution, but only the next step onwards.

* * *

Turning to Hungary and the revolution that tormented that unhappy land, we get nothing but horror. In the overwhelming emotions that Cécile Tormay records from day to day there is only vindictiveness. It is to be expected that so close to the battle front violent reactions spring to mind. *An Outlaw's Diary* is a burst of hysterical feeling tempered not at all by any perception of the "other man's" point of view. A royalist, she does not hesitate to stress and restress the bestiality, the executionary fervor of the party in power. But she incautiously notes that many of the executioners of the red régime were themselves destroyed as soon as the royalists seized power again. And so it goes the world over. "Me and Mine" is still the foremost interest.

One is much more impressed with the restraint and fairness in the first two books than with the personal sufferings, acute as they may have been, of Miss Tormay.

A FRAGMENT

Ariel. The Life of Shelley. By André Maurois. Translated by Ella D'Arcy. New York: D. Appleton and Company, 1924. Pp. 336.

Over the dry bones of contemporary history, the sinews of half alive letters, Maurois has created his Ariel. The life of Shelley exhales at least the essence of one man's dream.

The figures surrounding Shelley come very close to us. He, the erratic, the childlike, with his perpetual return to the nursery triangle, nevertheless stands out a far more vivid figure than ever before. There is no mention of his work in the biography. Yet the spirit of it has given the breath of life to Maurois's hero.

OLD NEW YORK

Old New York. False Dawn—The 'Forties; The Old Maid—The 'Fifties; The Spark—The 'Sixties; New Year's Day—The 'Seventies. By Edith Wharton. New York and London: D. Appleton and Company, 1924. Pp. 143-191-109-160.

Edith Wharton's four short novels, uneven as they are in substance, nevetheless succeed in their aim of giving historical flavor to a study of times long past.

False Dawn has the hackneyed theme of a prophet unrecognized in his own time. *The Old Maid* is the best of the stories, a powerful bit of lift,—two women and a daughter. An intricate, marvelous design that recalls the absorbing cruelty of *Ethan Frome*. A solution that admits of a hundred possibilities, and none. A story to make the possession of the whole set immensely worth while.

The Spark employs again a device used in the first story, acquaintance with a great man, in the first instance Poe, in the second, Walt Whitman. The easygoing man with the wildcat wife flares into action with the spark of remembrance of the ideas of the rough gentlehanded man who nursed him during the civil war. Though the ideals shape his life he is shy of meeting them face to face. Respectability versus reality—and the conventional the inevitable winner!

New Year's Day is the story of a woman who sells herself to provide a loved husband with necessities in his illness. She courts ostracism, yet she is absolutely true to herself. More than anything, the story comments on the limited field of enterprise open to women in the last century.

Medicoliterary Notes.

The Yellow Dragon, by Arthur Mills (London, Hutchinson), is a "real thriller" for a winter's night by the fire. It is a picturesque yarn of China, with a mysterious Chinese villain playing against several Britishers.

* * *

A London newspaper reports that so great has become the automobile peril in that erstwhile land of quiet lanes and remote byways, that people walking at night on busy highways wear over their shoulders small red glass disks that reflect the lights of automobiles approaching from behind, thus indicating to the drivers that a pedestrian is ahead on the road.

* * *

The cultivated strawberries now grown in Europe and America owe their size to their Chilean ancestors. Up to 1714, large fruited strawberries were not known in Europe, the native berries being small but of good flavor. In that year, a Frenchman brought plants from Chile. These were crossed with native varieties and with the Virginia strawberry introduced into Europe early in the previous century. By this crossing, plants were developed which combined large size with delicate flavor.—*New York Times.*

The New School for Social Research of New York City is offering this year a number of practical courses. In addition to that on applied psychology previously mentioned in this column, a course on evolutionary biology was given in October by Julian Huxley, of Oxford University; other lecturers are Dr. Frankwood E. Williams, medical director of the National Committee for Mental Hygiene; Dr. Douglas Thom, Dr. Bernard Glueck, Alexander A. Goldenweiser and Joseph K. Hart.

* * *

According to press reports from Paris, from now on divorce seeking spouses will have to stage their last fights outside the walls of the Palais de Justice. It seems that from time immemorial the men's and women's waiting rooms of this court have been the scenes of warring couples, staging a last conflict for marital rights and incidentally affronting the dignity of the Law, which was powerless to separate them, to say nothing of having other things to do. So the Law has had erected between these waiting rooms in the divorce section of the courts great iron grill work gates, the keys of which are entrusted to an attendant whose business it is to discriminate wisely.

* * *

The *Almanach de Gotha,* apparently in despair over the recent debacle of royal crowns in Europe, has turned to Asia and Africa, and in its latest edition shows that there are still some sovereigns left. Japan, which until 1922 was relegated to the section of the Almanach devoted merely to high officials and statistics, now has its royal family listed among the best, as is the case with other Asiatic rulers, once given second rank, such as the King of Siam and the Sultan of Zanzibar. For some strange reason, the Sultan of Turkey has always been listed among European royalty. From such high estate has fallen the publication which once dared to ignore the great Napoleon as an upstart unworthy of mention!

* * *

Hope and love—not lust—and reverence for human nature the essential parts of romanticism, are greatly needed in postwar England. No such signs of spiritual revival are clearly traceable in the chaos and babel the war has left behind. "We see not our tokens; there is not one prophet more." Perhaps he is among us somewhere, unknown; he may be a schoolboy or an apprentice. When he comes I am disposed to think that he will choose to speak to his generation neither from the pulpit, nor from the platform, nor

from the printed page, but from the stage. A great dramatist might help us to find our souls.—*Dean Inge of St. Paul's, in the Morning Post.*

* * *

A remarkable collection of Nelson papers, extensive enough to fill fifteen folio volumes, has recently come to light. They contain material relating to the victualing of Nelson's Mediterranean fleet during the Napoleonic Wars, and medical reports upon the condition of the men. Nelson was a zealous advocate of fresh provisions at sea, and the papers just discovered give the actual number of oxen bought, how much beef they yielded, and the number of pounds of onions and other vegetables and of oranges and lemons supplied to the six thousand men that manned Nelson's ships. Beef cost about eight cents a pound, and wine about twenty-five cents a gallon. Apparently only a small quantity of salt provisions was consumed. There was one short outbreak of scurvy in the winter of 1804-5, when the Spanish market for provisions was temporarily closed, but in general the health of the men was uniformly good. The chief diseases, besides the scurvy already mentioned, were fevers and lung diseases. There was a good deal of rheumatism, probably the feverish colds reported were influenza. The highest number of sick cases at any one time was 268. The average was below 200, and the deaths on board ship were about one per cent. per annum.—*Living Age.*

* * *

In a recent issue of the *New York Times,* Joseph B. Gilder writes an interesting account of *Folk Who Have Lived More Than a Century.* The writer states that for several years he has been keeping tab on centenarians. He outlines for us the career of Thomas Parr, the most famous of England's old men, who supposedly died at the age of 148, and upon whose remains Harvey was permitted to make an autopsy, discovering the organs to have been in a most remarkable state of preservation. But China can go England one better, for, according to tax records in that country, she now has one Yuan Kwo-chang who is approaching his 164th birthday. Josef Maga of Yugoslavia died this year at the age of 120. He became a father at 103. At about the same time died at the age of 117 James G. Sutton, of West Virginia, fellow citizen of John W. Davis, smoker and chewer of tobacco, but teetotaler. Among New Yorkers of advanced age is "case 15" in whom the United Hebrew Charities take a special interest because he has been an orphan for 105 years. He is still active and alert and earns a little by "visiting the sick and sitting up with the dead."

A good story with a psychopathological background is *Grievously Vexed* by Chris Sewell, reprinted in the *Living Age* for September 27 from the *English Review.*

* * *

All Rome is making elaborate preparations for the coming of the pilgrims in celebration of this jubilee year. New stores selling religious emblems and articles are being opened near St. Peter's, traffic improvements are being planned, streets and squares are being repaved and widened, rents are being doubled, tenants are being evicted to make room for better paying guests, hotels and boarding houses are being renovated, to celebrate the holy year instituted in 1300 by Boniface VIII. Dante was one of the first to come on that occasion.

As a result of the recent interchange of public health officers under League of Nations' auspices, it has been decided to establish an international society open to all medical officers of health who are taking part in the various interchanges organized by the League. A provisional committee composed of members from the leading countries of Europe will draw up a constitution for the organization, which will have its headquarters at Geneva and will act as a medium of exchange information on all matters of public health.

* * *

Lovers of London will be glad to know that a new type of souvenir volume has arisen to take the place of postcards and strings of shiny photographs between red covers. This is *The Artist's London,* published by John Castle, and containing eight contemporary pictures by leading artists, prefaced by four essays on various characteristic aspects of the city and her life. Drinkwater discourses on London fogs, Wilfred Whitten writes about the city's links with the past, and, if the reproductions of the pictures are somewhat disappointing, the book is as a whole what the *English Review* calls it—"a jolly record of London and London life and types, excellently produced."

* * *

German red tape seems to be still functioning. When the dramatist, Ernst Toller, recently arrived in Leipzig after a five years' sojourn in a Bavarian prison, he was at once arrested by order of the chief of police of that city. It was explained to him at the police court that he was arrested under an order sent from Munich in 1919. He was immediately released when the ignorant chief of police was informed that he had already served a five year sentence.

* * *

About 4600 B.C. a public dispensary was established in Egypt, the medical attendant for which received the equivalent of $500 a year for his services. This was at that time about five times the amount received by a skilled laborer.

* * *

At the International Town Planning Conference held at Amsterdam, Holland, in July, one of the features was the study clubs conducted by H. V. Hubbard, professor of landscape architecture at Harvard. Among the topics discussed at the meetings were industrial and housing areas, drainage, transportation, parks, and recreation.

An important recent publication of Dutton is *Race Prejudice* by Jean Finot, translated from the French.

* * *

Anthologie des Ecrivains Morts à la Guerre is the title of a four volume work to be issued in Paris by the Association des Ecrivains Combattants, the first volume of which has recently been published. This includes representative excerpts from the works of 450 French writers who lost their lives in the World War. Each selection is preceded by biographical notes and a bibliography. The introduction states that poets, romancers, dramatists, journalists, historians, geographers, philosophers, exegetists, archeologists, and even those who had scarcely begun to follow in the footsteps of their elders, will be included without distinction, no matter what their opinions or beliefs.

* * *

Dr. Methodi Popoff, professor in the University of Sofia and Bulgarian Ambassador to Berlin, lays claim to having increased the yields of many crops, including cotton, cereals and tobacco, by from twenty to fifty per cent. by a process of chemical treatment of the seed. He has used various stimulants, such as magnesium chloride and a number of metallic salts which are poisonous to vegetable as well as to animal life when taken in large quantities. He immerses the seeds in the proper chemical solution, leaving them there for a fixed time. If left too long, the seed life is destroyed; if not long enough, the chemical is ineffective.

* * *

Booksellers report that the translated works of D. H. Lawrence are so much in demand in Germany that it looks as though he is destined to become the interpreter of the British to literary Germany. Germany now has a Saint Joan of her own,—*Gilles and Jeanne,* a play by Georg Kaiser, now being produced at the Dramatisches Theater in Berlin. The reviews attribute to it a very "Freudian" view point and treatment, and seem to indicate that the playwright has taken many liberties with historical facts. Kaiser, now more than fifty, continues to produce two interesting and entertaining plays each year.

* * *

Prof. Morris Lecot, of the University of Louvain, has recently been at work on a bibliography of books about Einstein and relativity. He has found the number to be 3,775, only 435 of which have been published in Germany. England has contributed 1,150, France 690, Italy 215, and Holland 126.

* * *

Recent books of interest are *The Little Girl,* published in Great Britain under the title *Something Childish,* a posthumous volume of stories by Katherine Mansfield (Knopf); and *Anatole France, Politique et Poète,* by Charles Maurras (Paris, Plon).

Abstracts from Current Literature

PEDIATRICS

Heredity and Diseases of Childhood.—Charles Herrman (*Archives of Pediatrics,* May, 1924) states that the subject of heredity has not been given the attention which it deserves. Unfavorable peculiarities and tendencies are handled early in childhood in order to prevent their further development. The inheritance of physical and mental peculiarities apparently follow the same laws. For the proper study of the laws of inheritance, complete family histories and pedigree charts are essential.

Tendencies and peculiarities, although on a hereditary basis and congenital, may not manifest themselves at birth, but may develop later when the individual is called to bear an increased burden, as a result of improper feeding, unfavorable environment, infection, or psychical shock. Inherited tendencies may manifest themselves in the appearance of one or more of a group of related conditions, in the vulnerability of a certain organ or system, or in the appearance of congenital deformities. Good health and nutrition do not necessarily go hand in hand with resistance to infectious diseases. The ability to develop active immunity appears to be distinct for each infectious disease, and is probably on a hereditary basis. The ability to develop antitoxin in diphtheria acts as a dominant factor. The germ plasm, although a part, is distinct from and to a great extent independent of the organism itself.

The normal intact placenta acts as an efficient barrier against the transmission of injurious substances to the fetus. In twins we have the best opportunity to study the relative importance of heredity and environment in the development of human beings. Acquired characteristics are not inherited. The environment may, however, modify, hasten, retard, or inhibit the development of latent qualities. Prenatal care of the mother, although of great value, has definite limitations as far as the development of the fetus is concerned.

We can treat syphilis in the mother, detect disturbances in renal function, and pelvic deformities, but certain fundamental defects, which have their origin in the germ plasm, cannot be influenced. At present only the worst kind of mating can be prevented by law. The best can be encouraged. In addition to the present restriction of foreign parentage in numbers, an intelligent selection of immigrants should be made abroad.

Diagnosis and Treatment of Pyelitis in Infancy and Childhood.—Rowland G. Freeman (*Archives of Pediatrics,* March, 1924) states that a diagnosis of pyelitis should always be confirmed by a bacteriological examination of the urine. Catheterization in the female is not necessary and the urine may be obtained for such examination by the following procedure: The labia of the child should be separted and **the vulva carefully washed** with soapy water, rinsed with clear water and dried with a clean towel. The urine should be passed into a vessel that has been rinsed with boiling water, put into sterile bottles with corks that have been sterilized, kept cold until planted, and planted as soon as possible. Such urine when intelligently collected has a negligible external contamination. The treatment should be aided by proper regulation of the diet and by testing the reaction of all urine passed. The child should be considered cured only when pus has disappeared from the urine and when a sterile specimen of urine has been obtained.

Pyelitis in Infancy and Childhood.—H. J. Gerstenberger and S. A. Wahl (*Ohio State Medical Journal,* June 1, 1924) write that the term pyelitis at the present time really includes inflammation in one or more of the following locations—bladder, ureter, kidney pelvis and the kidney itself. Erratic change of disposition is one of the outstanding symptoms and one that should direct our attention to an investigation of the urinary tract. Fever is present in almost every case, while the same is true of socalled dyspepsia, which may be parenteral from the urinary tract, or may, on the other hand, be the primary and predisposing factor in the production of the pyelitis. Vomiting is common but subjective pain is rare, although in many cases one can make out tenderness in the renal region in the back. Chills, in the writer's experience, are not common symptoms nor can the kidney be palpated. Pus in the urine is after all the only pathognomonic symptom and in a typical case many leucocytes may be found with the low power of the microscope either clumped or separate. As to treatment there are two main drugs advocated, namely, urotropin with acid sodium phosphate on the one hand, and potassium citrate or the alkaline treatment on the other. The latter is preferred by the authors and they give twenty grains of potassium citrate every hour for six doses; every two hours for two or three days; every four hours for five or six days more, and then four times a day during convalescence.

Bacterial Content of the Urine in Children, with Special Reference to Pyelitis. — W. Morgan Hartshorn (*Archives of Pediatrics,* March, 1924) found that in healthy children the urine is free from bacteria in at least one half of the cases. Cultural growth in specimens obtained with sterile precautions is slightly in excess of that obtained by catheterization. For bacteriological examination of the urine, catheterized specimens are desirable but not essential for practical purposes. Children suffering from pyelitis should not be discharged as cured until cultured specimens of their urine are free from bacteria. The urine obtained under sterile precautions or by catheter contain a far greater number of bacteria in pyelitis than in any other disease studied.

Wasting Disorders of Early Infancy.—Leonard G. Parsons (*Lancet,* April 5, 1924) calls attention to the fact that fat indigestion occurs in infantile atrophy under two conditions: 1. When diarrhea develops. In these cases as a result of peristaltic hurry, rapid passage through the intestine occurs, and fat splitting may be poor. 2. When high fat content dried milks are given. In these cases fat splitting is always good, the stool is a large one, and contains much soap and free fatty acid. The treatment of artificially fed children in the first of these groups consists in putting them on a low fat dietary, and giving them carbohydrate in the form of one of the less fermentable sugars, e. g., dextrimaltose. The low fat dietary can be obtained by giving them skim milk, or a mixture of skim and whole milk; at times a condensed, sweetened milk, diluted so as to give a low fat content, is found very useful, or one of the artificial foods used in the same manner. Protein milk has also proved valuable on occasions. When the diarrhea improves, the fat content should be increased again, until the child is on a normal milk mixture. A short preliminary period of starvation is often useful in these cases, particularly if the onset of diarrhea is sudden (or possibly infective), but many children are so enfeebled that they are unable to stand this treatment. The treatment of the second group consists in giving a lower fat content dried milk, or substituting an ordinary cow's milk mixture for the dried milk.

Deficiency of Sunlight as a Morbid Factor in Early Childhood.—Woringer (*Journal de médecine de Paris,* June 7, 1924) calls attention to the marked influence of light upon spasmophilia in nurslings. Sunlight or the ultraviolet rays bring about permanent cessation of the convulsions in a few days, and the hypocalcemia which always accompanies spasmophilia and bears a relationship to the excessive neuromuscular excitability is corrected permanently without any treatment other than heliotherapy and actinotherapy. Sunlight seems an indispensable factor in the normal development of the child, and where it is lacking, a species of deficiency disease results. The following facts support the origin of spasmophilia in lack of light: 1, the periodical seasonal appearance of the disease in the winter and spring; 2, its particular occurrence in districts receiving little direct sunlight and its almost complete absence in the tropics; 3, its prevalence among the poorer classes, living on narrow streets and in unhealthy dwellings, and 4, the curative and preventive influence of light. Rickets and spasmophilia are closely related, and a combination of the two disorders has at all times been noticed. Like causes bring on the two diseases; other factors, such as the diet, digestive disturbances, infections and intoxications may intervene, but only in a secondary way, acting in conjunction with the deficiency of sunlight. Other morbid states of childhood may be ascribed to the latter factor, viz., infections of the respiratory tract—common in rachitics—and

otitis media, which runs an especially severe course in spasmophilics and is quickly recovered from under actinotherapy. These facts warrant the thought that deficiency of sunlight is accompanied by a special susceptibility and a lowering of resistance to bacterial infections, especially pneumococcic. Infants should be exposed to the sun's rays from the first few weeks of life. Among the poorer classes, the mothers should be particularly advised to take their infants into sunny places. Among those whose dwelling receives direct sunlight, the advice should be given to expose the baby directly in the sunlight and not behind windowpanes, the glass of which absorbs the greater portion of the especially useful ultraviolet rays. When sunlight is lacking in the winter, the mercury vapor quartz lamp should be brought into requisition.

Rickets and Parathyroids.—F. S. Hammett (*Endocrinology*, July, 1924, vol. 8, p. 557) shows that retardation of bone ossification in rickets is due to deficient calcium, in parathyroid states of underfunction to deficiency of phosphorus in the organism, the two being opposite phases of the phosphorus calcium balance.

Late Rickets and Osteomalacia.—H. S. Hutchison and Grace Stapleton (*British Journal of Children's Diseases*, April-June, 1924) state that in osteomalacia the existence of pregnancy does not produce symptoms differing in any essential way from those occurring in nonpuerperal cases. The presence of pregnancy, therefore, does not entitle osteomalacia to be regarded as a separate entity. The existing differentiation of early rickets, late rickets, and osteomalacia according to age incidence does not appear to be justifiable. Evidence points to the conclusion that these conditions are identical and represent rickets at different ages. The primal causal factor of early rickets, late rickets and osteomalacia is environmental. While lack of sunlight is considered a factor of importance, diminution in muscular activity must be looked upon as of prime importance. Pregnancy is of secondary importance in the causation of osteomalacia.

Acidosis in Relation to Acute Rickets.—Norman Burgess and A. A. Osman (*Lancet*, February 9, 1924) show that the results of determinations of the plasma bicarbonate and acetone bodies in the blood and urine form an interesting comparison with figures recently obtained in a series of cases of diabetes mellitus. In the latter it was found that the diminution of the plasma bicarbonate corresponded fairly closely with the total acetone bodies present in the blood; this is far from being the case in acute rickets, although in each case there was marked diminution in the alkali reserve. In two of the three cases reported, no acetone bodies were present, while in the other case, although the plasma bicarbonate was still lower eleven days after the first observations were made, the ketosis disappeared after four days and did not reappear. So far the author's results would tend to show that there is a severe acidosis in acute rickets in which the acetone bodies play no part. This would lead to the conclusion that the acidosis is due to one or both of the following factors: 1, loss of bases by some other channel, as the feces or urine; 2, some other acid bodies present in the blood.

Instability of the Plasma in Sick Infants.—G. Török (*Monatsschrift für Kinderheilkunde*, April, 1924) found that in individual newborn infants the Gerlóczy reaction of the instability of the plasma is positive and most pronounced on the third to the fourth day of life. As the destruction of leucocytes is very marked in certain newborn infants, which also reaches its peak on the third or fourth day, it is possible that this instability may be attributed to the globulin set free by the leucocytes, which in some respects is similar to the nucleoproteins. The Gerlóczy reaction (precipitation by saturation with salts) is negative in healthy infants. Parenteral infections produce less change in the colloidal condition of the plasma in breast fed infants than in those artificially fed, and in older infants less than in younger infants. Of the parenteral infections, rhinitis and angina do not alter the instability reaction of the plasma, febrile bronchitis alters it but little, and pneumonia and suppurations alter the plasma reaction of the blood to the same very great extent as some skin diseases, like pemphigus neonatorum and Ritter's and Leiner's diseases. The reaction is positive in tuberculosis and syphilis. It is negative in rachitis and exudative diathesis. The reaction is negative in slight digestive disturbances, but positive in severe reactions.

Acute Appendicitis in Childhood.—F. Beekman (*Annals of Surgery*, April, 1924) sums up his case findings as follows:

1. The earlier diagnosis is made and operation performed, the lower is the mortality, the fewer are the complications and the shorter is the convalescence.
2. Acute appendicitis in children is more frequent as adolescence is approached.
3. With the exception of children under five years of age, in whom it is extremely high, the mortality is about the same as among young adults.
4. The disease is found twice as commonly in boys as in girls, the mortality being about twice as great among girls as boys.
5. Perforation of the appendix with spreading peritonitis or abscess formation occurs more often in children than in adults.
6. Immediate postoperative complications are as commonly found in children as in adults, with the exception of secondary abscesses, which are seen more often.
7. Incisional hernia follows operation in children more often than in adults. Sloughing of muscles and aponeurosis, secondary abscesses and partial evisceration of portions of the abdominal contents appear to be the causative factor.
8. Mistakes in diagnosis would seem to be inevitable and it would appear better to err by operating.

Infant Welfare Movement.—W. M. Feldman (*British Journal of Children's Diseases*, April-June, 1924) recommends the future development of the infant welfare movement along the following lines: 1. There should be provision for free continuation classes in infant welfare and prematernity, which all girls should be made to attend. 2. General and child hygiene should be a subject of tuition in all schools, especially secondary schools. 3. A course, including a consideration of the important causes of antenatal and postnatal infantile mortality and their prevention, should be given to medical and postgraduate students, as well as the subjects of the physiology, pathology and hygiene of antenatal and early postnatal life in their theoretical and practical aspects. 4. Good, commodious, and hygienic houses should be provided at a reasonable rental. 5. Greater cooperation between infant welfare centres and the neighboring practitioners should be encouraged. 6. The infant welfare and antenatal centres ought to have full time medical officers who have had special training in the physiology, pathology and hygiene of the various stages of child life, and who are capable of carrying out legitimate research in the physiology of infant nutrition. 7. The antenatal clinics should be merely branches of the infant welfare centres and not separate entities, and there should be an adequate number of antenatal beds or wards for the purpose of treating any discovered abnormality of pregnancy as well as for research purposes. 8. Prenuptial clinics, where persons of both sexes can get advice as regards their fitness to marry, both from the genetic and constitutional standpoints, should be established.

Diarrhea in Infants.—In a symposium on diarrhea (*Southern Medical Journal*, August, 1924) Wilburt C. Davison discusses the bacteriology of diarrhea in infants and expresses the opinion that although there is as yet no absolute proof of the etiology, it would seem probable that infantile diarrhea, except bacillary and amebic dysentery, is not a primary bacterial infection, but that, as a result of changes produced by external heat or by some other cause, the gastric acidity and motility and the gastric and duodenal enzymes are reduced. Undigested and unabsorbed food is then fermented by the stool organisms, either in the small or large intestine, into irritating end products which accelerate peristalsis and produce diarrhea.

Owen H. Wilson, on the other hand, maintains that the exciting cause of infectious diarrhea is undoubtedly an infection wtih some pathogenic organism or organisms, and in preventing this, the improved methods of handling milk, the technic of feeding, the "swat the fly" campaign, the widely spread instruction in general cleanliness and hygiene through the public nurses, and the extended use of boiled milk have been responsible in great measure for the decrease in the number of infectious contacts.

N. C. Womack discusses the treatment of extremely serious cases and emphasized the need of complete rest as essential.

Ralph C. Spence and Earl B. McKinley report twenty

cases of bacillary dysentery treated with the bacteriophage. The mortality was only ten per cent. They believe that the therapeutic use of the bacteriophage in the treatment of acute bacillary dysentery in children will greatly lower the mortality; that the earlier in the course of the disease the treatment is begun the better are the chances for an early recovery, and that in those cases which recover the treatment with the bacteriophage will greatly shorten the duration of the disease.

In the discussion several speakers agreed with Dr. Womack in his condemnation of an initial purge. As Dr. D. Lesesne Smith put it: "The child gets a little sick and is given calomel and castor oil and his resistance is lowered. We have diarrhea following the administration of these drugs."

Significance of Protein Fractions of the Blood Plasma in Infancy.—J. Duzár and St. Risznyák (*Monatsschrift für Kinderheilkunde,* April, 1924) assert that the serum of infants is more stable in its composition than in adults. The maximum of the stability of the plasma occurs in about the second month of life. The globulin content of the serum runs parallel with this. In icterus neonatorum there is a moderately increased amount of total albumin and the portion of fibrinogen is increased. In syphilis there is a marked increased of fibrinogen and also in intoxications, but there is a diminution in the amount of the serum globulin in proportion to the albumin. On the other hand, infectious intoxications show a high globulin albumin quotient very early in the disease. Bronchopneumonia shows a marked increase in the globulin.

Congenital Defects of the Skin and the Scalp in the Newborn.—Hans Otto Neumann (*Zentralblatt für Gynäkologie,* March 15, 1924) maintains that these congenital defects result from adhesions of the skin with the amnion as a result of developmental disturbances or inflammatory processes. At the sites of such adhesions the formation of pavement epithelium does not occur. Usually these adhesions are stretched into bands with the growth of the fetus and the increase of the amniotic fluid. Intrauterine scars may result from their rupture as a result of a sudden intrauterine movement of the fetus. If the rupture occurs during delivery a fresh defect is observed on the child. These amniotic adhesions may result in extensive injuries of the fetus, such as cleft formations around the face, and even amputations of fingers, toes and extremities. Broad adhesions may result in ectopy of the abdominal viscera, umbilical hernia, etc.

Impetigo Contagiosa in Children.—D. T. Smith and E. L. Burky (*Bulletin of the Johns Hopkins Hospital,* March, 1924) base the present study on nine cases of impetigo and one of chickenpox in which the vesicles resembled those of impetigo. Hemolytic streptococci were found in six cases, and hemolytic staphylococcus aureus in three; while the culture from the case of chickenpox was negative. No serological unity was found among the streptococcus strains isolated, and the sugar fermentation tests also showed an absence of unity. The staphylococci were also heterologous. These cases were treated routinely with an ointment of ammoniated mercury one third the usual strength, which is effective for the streptococcus, but not for the staphylococcus cases. Gentian violet was effective in the treatment of both.

Acetonemia and Volvulus of the Small Intestine in Children.—F. John Poynton (*Lancet,* May 24, 1924) calls attention to the fact that acetonemia may be associated with various pathological conditions. Among these he includes volvulus of the small intestine, in which cases the acetonemia reaches such proportions as to dominate the diagnosis. In this group of cases starvation is a feature. When the obstruction is high and vomiting is an urgent and early symptom, acetonemia becomes rapidly apparent and the drowsiness, loss of strength, and extreme illness may then be attributed to a primary cyclical vomiting. The symptoms are most probably brought about by the serious results of an obstruction high in the intestinal tract.

In childhood, acetonemia may occur under very different conditions. It may be a fleeting event and not perceptibly alter the outlook. If persistently looked for it may be found to have no serious clinical significance. In other cases, as in diabetes, it may have the greatest importance as a danger signal. In yet others it may be the prominent feature in a recurrent illness which may, though rarely, prove fatal without, with the exception of the liver, showing any pathological signs of responsibility for death. Finally, it may prove a cause of grave errors in diagnosis by its prominence in the cases mentioned. The other responsible factors are the absence of abdominal physical signs, the occurrence of only partial constipation, and the history of repeated attacks with complete recovery between times. The moral is that acetonemia in childhood should never be regarded as a disease, but always as a symptom.

Clinical Experiences in Organotherapy with Special Reference to the Stimulation of Body Growth.—Fourteen case histories are recorded by Theodore A. McGraw (*Endocrinology,* March, 1924) the patient in every case being a child suffering from retarded physical development, either with or without definite symptoms of endocrine disease. In presenting therapeutic suggestions he says: "While each deficiency case is usually pluriglandular, one gland generally stands out as primarily and chiefly affected. Treat this deficiency first by administering solely the animal extract of that gland; then, if necessary, add one at a time the extracts of the glands secondarily affected to the prescription."

HERNIA

Surgical Anatomy of Femoral Hernia.—H. S. Souttar (*British Medical Journal,* March 1, 1924) mentions the following points of practical importance in the diagnosis and treatment of femoral hernia: 1. In most cases the presence of a femoral hernia is characterized by the appearance of a soft, spherical swelling in the angle between Poupart's ligament and the tendon of the adductor longus. 2. The pubic spine is not so satisfactory as Poupart's ligament itself as a boundary between inguinal and femoral hernias. 3. Gimbernat's ligament is not directly concerned in the strangulation of a femoral hernia, and its division serves no useful purpose, and may be dangerous.

Hernia Through Foramen of Winslow.—A. Ullman (*Surgery, Gynecology and Obstetrics,* February, 1924) reports on several cases of this rare disease, saying that preoperative diagnosis has never been done, and that in many instances it has passed as simple intestinal obstruction under operation. In conclusion he says that one might ask whether a preoperative diagnosis would ever be made of a hernia strangulated through the foramen of Winslow and would it be differentiated from other internal herniæ? That remains to be seen. At present, the important point is to diagnose intestinal obstruction and to operate at once. In this way the prognosis in herniæ strangulated at the foramen of Winslow can no doubt be rendered more favorable.

Recurring Hernia of the Diaphragm.—P. E. Truesdale (*Annals of Surgery,* May, 1924) says that recurrence of hernia of the diaphragm after many months is a liability irrespective of the method or suture material employed in repair of the hernia orifice. Deficiency in the musculature of the diaphragm exists as a natural sequence of prolonged limitation of function or of trauma to terminal branches of the phrenic nerve, or both of these conditions. The method of approach in dealing with hernia of the diaphragm may be selected to best advantage after determining the direction of greater accessibility, and conditions to be met above and below the diaphragm. Early operation and the avoidance of such activities as produce unusual increase of intraabdominal pressure is the only safeguard against recurrence.

Inflammation in Sacs of Inguinal Hernia.—G. M. Smith (*Annals of Surgery,* February, 1924) summarizes his findings as follows: Microscopically, inguinal hernial sacs may be divided into two groups. Group 1, the fibrous hernial sac, representing the usual hernial sac of infancy and childhood and the more common form seen in the adult. It has a tendency to become thickened in the progress of its development. Group 2, the fibrous fatty hernial sac. There is a tendency of fatty tissue to replace the fibrous and elastic tissue situated below the lining endothelium. Inflammatory changes were found in thirty-seven out of two hundred and fifty enguinal hernial sacs removed at operation. Inflammation occurred under a variety of conditions: in the form of aseptic inflammation, infectious (tuberculosis), or by parasites (trichina spiralis). A subacute inflammation of the subendothelial connective tissue of an inguinal hernial sac may be associated with the onset of hernia following muscular effort.

Right Diaphragmatic Hernia.—S. Fineman and H. M. Conner (*American Journal of the Medical Sciences,* May, 1924) report on an unusual case as follows: The incidence of diaphragmatic hernia at the Mayo Clinic is one in twenty-three thousand cases. The case of diaphragmatic hernia reported was on the right side, and in all probability of the short esophagus type. The intragastric tension in this case was found to be the reverse of what is usually found in a normal person. In such hernias, on account of the congenitally shortened esophagus, we believe complete reduction of the stomach from the chest into the abdominal cavity is impossible. Therefore, for the sake of rational management, every patient with diaphragmatic hernia involving the stomach should have a careful roentgenologic examination with the specific object in mind of determining, so far as possible, the length of the esophagus.

Fascia Plication for Inguinal Hernia.—J. A. Pettit (*Surgery, Gynecology and Obstetrics,* May, 1924) says that if the general principles of plastic surgery are applied in operating on inguinal hernia, better results may be expected. The sustaining tissue in such operations is fascia. As the fibres are sewed longitudinally they have a tendency to spread, especially if the fascia is already attenuated. A complete plication or overlapping insures a maximum permanency of security, and avoids the tendency of the fibres to spread. By high transplantation of the cord in the new fascial canal, the possibility of another peritoneal protrusion is minimized.

The type of suture described gives a minimum amount of constriction to the fascial fibres and at the same time a maximum coaptation. To secure an early as well as firm fascial cohesion it is important to cleanse the fascial surfaces thoroughly of all fat and areolear tissues, otherwise the sutured areas may slip as would a pseudoarthrosis. The high curved incision in the skin and fatty layer removes the wound the greatest distance from possible sources of postoperative contamination.

Operations for Inguinal Hernia, Especially in Infancy.—Gustav Ranft (*Monatsschrift für Kinderheilkunde,* March, 1924) summarizes his views on the incarcerations occurring in infancy as follows: 1. Every inguinal hernia occurring in infancy should be subjected to radical operation. 2. Every case of incarceration that cannot be reduced should quickly be put into the hands of a surgeon. An attempt at careful taxis is allowable, but if it does not succeed at once any further waiting and further conservative treatment is a crime against the life of the child. 3. Every successful attempt at taxis should be followed in a few days by a radical operation. 4. The results of operative interference for incarceration in infancy are good.

The claims for early operation are fortified by the following guiding principles: 1. The radical operation is necessary because a spontaneous recovery cannot be expected, because the child's development is interfered with by the rupture and because the life of the child is endangered. 2. The truss cannot be considered as a complete substitute because it does not definitely lead to a permanent recovery and because it is inconvenient, troublesome and even dangerous in the hands of the inexperienced and also because it lessens the chances of the operation. 3. The radical operation should consist only of a high ligature, all plastic procedures are unnecessary in simple cases and the division and suture of the external aponeurosis should be avoided because they increase the danger of recurrence. For gliding hernias or in agglutination between the hernial sac and abdominal contents, the Kocher invagination displacement procedure seems to give better results in selected and simple cases. 4. The results of the radical operation and early surgical interference are good. 5. The main requisite for every herniotomy in early infancy is an otherwise healthy state of the child. The digestive capacity should be arranged so as to be on the increase. 6. If for some reason a radical operation is impossible, no local treatment, except the necessary care of the skin, should be given to the hernia. 7. The indication for herniotomy should be left to the surgeon who specializes in the surgery of infancy. 8. Only in this way can the incarcerations occurring in fancy be reduced to a minimum and deaths avoided. 9. In every case of incarceration in infancy the author utilizes taxis and possibly also the hanging position, the hot bath, with avoidance of any force. If these measures fail, herniotomy and a radical operation should be done immediately.

Postoperative Recurrence of Inguinal Hernia.—A. S. Morrow (*Annals of Surgery,* October, 1923) believes that the operative cure of inguinal hernia is not the simple procedure that many surgeons regard it, but is an operation requiring sound surgical judgment, as well as considerable technical skill. Oblique and direct hernia should be looked upon as two distinct conditions, in both of which recurrence is probably more frequent than was formerly recognized—this being especially true of the direct form. Improvement in operative results is not likely to come from the development of an operation based upon new principles, but in the elimination of what are considered to be frequent causes of failure to obtain a permanent cure. These are: Subjecting to operation patients in whom, on account of the type of hernia, and the condition of the parts that must be utilized for repair, there is small chance of obtaining a permanent cure. The use of an operation which, while adequate in some cases, fails to meet the indications in an individual case. The failure thoroughly to remove the sac or to recognize and remove a double sac. Repair of the canal under tension. Injury to the nerve supply of the inguinal region. Infection. Separation of the repair structures from a failure of the sutures to hold, or from the strain of postoperative vomiting.

Repairing Inguinal Hernia With Living Sutures.—J. McEachern (*Annals of Surgery,* May, 1924) offers the following technic, which he has found by experience to be highly commendable for the satisfactory closure it gives.

A five inch incision is made in the usual site terminating slightly below the pubic spine. The external ring and the tendon of the external oblique up to its origin from the fleshy belly of the muscle is cleared. One blade of a pair of blunt scissors enters the external ring near its inner pillar, and with the scissors following the direction of the fibres the tendon is slit up to its origin from the muscle. A second incision one quarter inch internal to the first is made through the tendon with a scalpel, at a point about an inch above the pubic bone. The blade of the scissors is inserted into this incision and carried parallel to the first incision up to the muscular fibres where the strip of tendon is severed from its muscular attachment. In completing the freeing of the strip of tendon below, the incision at a point about half an inch from the pubic bone bends inward, thus giving the strip of tendon to be used as a suture, a wide attachment to the bone.

The free end of the suture thus obtained is threaded on a curved needle with a large eye, and the end secured against slipping out with a ligature of fine catgut. The needle is then passed through the conjoined tendon close to the pubis. This results in strain being applied in the normal direction of tendon fibres, and should ensure that the suture will not be pulled from its bony attachment. The needle now picks up the reflected portion of Poupart's ligament and the periosteum covering the pubic bone close to the spine. The internal oblique is drawn down to Poupart's ligament with additional stitches, the end being secured by drawing the suture through itself, splitting the ends and tying them across in a triple knot after the method of Gallie. After the knot is tied, a needle threaded with No. 0 chromic catgut is passed through the knot and tied. Additional security against the knot slipping can be obtained by passing the needle beneath the suture or through the adjacent portion of Poupart's ligament and tying down the ends. The edges of the external oblique are now sutured external to the cord in the usual way.

In the cases in which the author used the method this single suture taken from the external oblique tendon was long enough to close the defect effectively. However, if an additional suture to close the upper end is required it can be obtained by dissecting up the external oblique tendon from the underlying tendon of the internal oblique as far as the median line. A slip of the internal oblique tendon is then cut out, leaving its muscular attachment undisturbed. This suture is threaded on a needle as before, the needle is passed through the cut edges of the internal oblique tendon, and then through the loop, thus forming a knot which prevents the suture pulling away from the muscular attachment. The needle is then passed through Poupart's ligament and up through the internal oblique and the end secured as before. The gap in the tendon of the internal oblique from which the suture has been taken is closed with No. 1 chromic catgut.

BLOOD POISONING FROM PULLING TOOTH HELD ACCIDENT

The Texas Court of Civil Appeals holds, Francis v. International Travelers' Assn., 260 S. W., 938, that infection, blood poisoning and death, resulting from the pulling of a tooth, is an unusual, unexpected, and unlooked for occurrence, and is covered by a policy insuring against death from injuries received "through external, violent and accidental means."

DEATH FROM FRACTURED SKULL OR FROM ARTERIOSCLEROSIS?

A workman afflicted with arteriosclerosis was injured by falling and striking a concrete floor with the back of his head. He died fifteen months later, the immediate cause of the death being a severe hemorrhage in the brain. There was evidence tending to show that when he fell his skull was fractured, a slight hemorrhage in the brain followed, and that the fatal termination of his disease was hastened by the accidental injury to his head. The Minnesota Industrial Commission found that death was caused by the accidental injury. Under the evidence, the Minnesota Supreme Court held, Maxon v. Swift & Co., 198 N. W., 133, that the finding could not be held to have been the result of speculation and conjecture, and affirmed the award.

DISCRIMINATORY CLASSIFICATION IN ILLINOIS MEDICAL PRACTICE ACT

In proceedings, under the Illinois Medical Practice Act of 1899, against an osteopathist holding licenses authorizing him to practise a system of treating human ailments without the use of medicine internally or externally and without performing surgical operations, and to practise midwifery without the use of any drug or medicine, or attend other than cases of labor, charging that he practised medicine and surgery by treating a woman's ailment by a surgical operation on her and administering pituitrin and strychnine, it appeared that the defendant had received courses of instruction, including the nature, use, operation and effect of strychnine and pituitrin in connection with and incident to surgery. The act of operative surgery charged was curetting the patient's uterus for the removal of morbid matter, consequent on an illegal act or operation performed by some other person. He did not administer any drug as a curative or remedial agency for a disease or ailment, but only as a part of and incidental to the surgical operation, either as a stimulant or by contraction of tissues, to secure successful results of the operation.

The Illinois Supreme Court held, People v. Graham, 211 Ill., 92, 142 N. E., 449, that, while the Legislature, in the enactment of such statutes, may provide for classes, so long as the classification is general and bears a reasonable relation to the purpose sought to be accomplished, any act of the Legislature which is merely arbitrary and discriminatory, where there is no substantial difference between the classes, and which abridges privileges of citizens or grants special privileges to classes, is in violation of constitutional rights.

The application of these principles was held to require a reversal of judgment for plaintiff in this case. "There was no provision of the act," the court said, "under which a license to practise surgery could have been given to the defendant. The right to such a license was limited to a class to which he did not belong, and as the law does not require a useless act to secure a right, the defendant was not called upon to apply for a license that could not be granted. The act was not void as to any person not deprived of a constitutional right, but was void as applied to the defendant deprived of such right."

RUPTURE OF ARTERY HELD ON MEDICAL TESTIMONY TO BE THE RESULT OF STRAIN

A claim for compensation under the Pennsylvania Workmen's Compensation Act was based on the theory that death of a mine car loader was due to rupture of a bloodvessel caused by extra exertion used in moving a partially loaded mine car along a track. Within from four to fifteen minutes after pushing the car, the deceased complained of a pain in his head and immediately fell forward in a semiconscious condition. He died the same day, the cause of death being diagnosed as apoplexy or cerebral hemorrhage.

Medical witness testified that deceased was not in good physical condition, being afflicted with arteriosclerosis, and that, owing to the lapse of time between the moving of the car and the indication of physical distress, they could not say positively that the exertion was responsible for deceased's death, being of opinion that a rupture of a bloodvessel would manifest itself in a much shorter time and perhaps have resulted in an immediate collapse. The furthest they would go was to say that the exertion could or might possibly have caused the fracture of an artery in deceased's head. This was held insufficient to show a causal connection between the effort used in pushing the car and the cerebral hemorrhage.

Two additional physicians called to testify at the rehearing placed an entirely different light on the situation. These witnesses said the undisputed facts clearly indicated that death resulted from the strain incident to assisting in moving the car, and that the interval of four to fifteen minutes, or even a longer time, before an outward manifestation of a rupture of a bloodvessel appeared, was not unusual, but merely signified the original break to be of slight character. This testimony was held, Samoskie v. Philadelphia & Reading (Pa.), 124 Atl., 471, to sufficiently support findings that the exertion required in moving the car produced an increase in blood pressure, which, in turn, resulted in the rupture of an artery causing death, and, inasmuch as the injury occurred in the course of deceased's employment, claimant was entitled to compensation.

EMPHYSEMA FROM INHALING SMOKE AND FUMES HELD AN OCCUPATIONAL DISEASE

The employment of an electrical engineer in a coal mine required his presence in rooms where electric generators were in operation and gave off smoke and fumes, especially when overloaded. On August 24, 1921, he inhaled an unusual quantity of such smoke and fumes while extinguishing a fire, and soon after had pains in the chest and shortness of breath, which condition gradually increased until total disability resulted at the end of six months. The Pennsylvania Supreme Court, Manchline v. State Ins. Fund, 124 Atl., 168, reversing an award of compensation, held that to connect the disease with the socalled accident required expert evidence, but that of the only medical witness warranted the conclusion that the inhaling of such vapors during a considerable period of time would be likely to cause emphysema, while the excessive inhaling thereof on a single occasion, would not although it might possibly do so. This was not sufficient to sustain the claim.

The medical evidence indicated that emphysema is normally of slow development and probably here came on gradually from continued contract with the smoke and fumes, in which case it was not an accident but the result of an accupational disease, and therefore not compensable under the statute.

A Study of History and Symptoms as a Practical Aid in the Diagnosis of Pulmonary Tuberculosis*

S. A. SLATER, M.D.,

Worthington, Minn.

The importance of the early diagnosis of tuberculosis cannot be too strongly emphasized. It matters not in what field of medicine you are engaged you may be the first to see the patient after he has become actively tuberculous. If you are able to make a diagnosis at this time or even have your suspicions aroused so that a diagnosis will be made you have rendered a real service. It may be that a patient first consults a surgeon for an operation. If active tuberculosis is present and not detected a surgical operation may prove disastrous much to the chagrin of the operator. The same may apply in other fields of medicine. It is not the purpose of this paper to bring out anything new in the diagnosis of tuberculosis nor in fact anything with which you are not acquainted. Its purpose will be to refresh your memories with what you already know and try to impress upon you the importance of using it, simple as it may seem, to bring about an earlier diagnosis for the benefit of the patient and your own satisfaction.

Do not conclude from these remarks that the diagnosis of tuberculosis is always easy. It is not, and it often taxes every means at our command to make a correct diagnosis. Its very nature makes the diagnosis hard at times. It may be of a very obscure nature, one patient presenting symptoms of one sort while in the next they will be entirely different.

There are two things necessary to produce clinical tuberculosis; first, infection with the germs and second, a lowered resistance. It has been proved conclusively that the germs alone will not produce the disease for many are known to be infected in whom it never develops. It is the lowered resistance which gives the germs already present a chance to get a foothold and produce active trouble. Even with one's greatest efforts many cases will reach the advanced stage of the disease before consulting the physician. On the other hand many patients under their care for one cause or another are permitted to go with the disease undiagnosed. These are the ones which should not be overlooked or allowed to reach the advanced stage. Most of these can be discovered reasonably early if only time and attention are given to looking for them. The fact that a patient has a definite disease other than tuberculosis does not exclude the latter. It is rather this patient who may have tuberculosis, for conditions are favorable for its development. This should be kept in mind especially if other symptoms are present or if the patient is slower than he should be in making a recovery.

Patients often drop the first physician who tells them they have tuberculosis and seek others until they have found one, it matters not whether he is a regular, an osteopath or a chiropractor, who will tell them they do not have it. It is to the advantage of the physician to make the diagnosis as early as possible and when he has done so to tell the patient the exact condition. The importance of informing the patient as soon as a diagnosis has been made cannot be overemphasized. No physician can get results in treatment or the cooperation of the patient in carrying out instructions and taking precautions until he first convinces him he has the disease and impresses upon him the seriousness of the situation. The idea of a physician saying, "I can't tell the patient for I feel that he will give up as soon as he knows his condition," is absurd. I have yet to see or even authentically to hear of a patient who died because of being told he had tuberculosis. This is the only way to get his cooperation. The patient should not be considered alone in this matter, many things have to be done for the protection of others, and this can be done by having the patient take the proper precautions. The importance of an early diagnosis cannot be denied neither can it be denied that too many patients are allowed to reach the far advanced stage or permitted to run active symptoms too long before being discovered. It should then be to the interest of all to familiarize themselves with the things which will help in making an earlier diagnosis and at a time when it will be of the greatest value to the patient and those with whom he associates.

*Read by invitation before the Hennepin County Medical Society, Minneapolis, September 12, 1923.

How can this be done? The principal means used in making a diagnosis are, a study of history, symptoms, physical signs, x ray and laboratory findings. Choosing these methods in the order of their relative value I would take first, symptoms, second, history, third, physical signs, fourth, x ray and last, laboratory findings. This is just the reverse of the views held by many physicians. Apparently there are many who feel that an examination of the sputum is all that is necessary. Some seem to think they have done their duty when they have obtained a specimen of something the patient expectorates, it matters not whether it comes from the mouth, throat, nose or lungs and sent it to the laboratory to be examined. If the report comes back negative the patient does not have tuberculosis and very likely another specimen is not sent. The finding of germs is proof of the presence of the disease. If they are not found it is not proof in itself the disease is absent. It is very hard to find the germs in the incipient case. Should one allow the patient to reach an advanced stage because the germs have not been found? This is frequently done and owing to the uncertainty of finding germs until the disease has become advanced is my reason for placing it last in value of the means at our disposal. The x ray is a most valuable aid in the diagnosis but when used alone would not be conclusive. Like physical findings it shows what has taken place in the chest rather than what is taking place. I was greatly amused recently when I read two papers written by the same man, but several years apart, on the use of the x ray. In the former paper he stated he could make an absolute diagnosis of tuberculosis with the use of the x ray. In the latter he had become modest enough to admit that it was of great help but should be used only with other means at our disposal.

Physical signs like x ray findings are of little value when taken alone. The more expert the examiner the less apt he would be to risk a diagnosis without something to corroborate the findings. I have mentioned the first three, laboratory findings, x ray and physical findings, more to warn of the danger encountered in depending on them for a diagnosis. The other two methods, history and symptoms, can be used by any physician, and found of practical value, who will give a little time to obtaining them. These alone will often give us sufficient information to arouse our suspicion when tuberculosis is present and if it is not possible to make an absolute diagnosis it will give an opportunity to refer the patient to one who can and before it is too late.

The value of a properly taken history is too often underestimated. It should be used more widely and with greater thoroughness. It is something that can be obtained by any physician although some may be decidedly more expert than others. Anything of as great value should be carefully studied and employed to the fullest extent.

Symptoms likewise can be obtained by all physicians who will take a little time to ask questions and listen to the patient's answers.

My selection of this subject for a paper was due to the fact that some of the earliest cases referred to me were sent by physicians who had never made an examination of the patient but became suspicious of tuberculosis as a result of a carefully taken history and study of symptoms. A physician whose hearing was impaired and who could not use the stethoscope or percussion satisfactorily once suggested to me that I write a paper dealing with the symptoms of tuberculosis. He like the physicians mentioned above who did not make physical examinations had become fairly expert in making a diagnosis on the history and symptoms.

The value of the history depends on how well it is taken. If the best results are to be had it should go into in the most minute detail and nothing should be taken for granted. The family history is carefully taken not on account of the old idea that tuberculosis is hereditary, but to ascertain if there has been any intimate exposure. To ask if any relative has ever died of tuberculosis is not sufficient. Begin with the grandparents and study each individually, learn the cause of death in each instance. If the nature of the disease cannot be ascertained, endeavor to learn if they had a chronic cough, suffered from asthma, bronchitis or a run down condition. If any of the family died of a disease simulating in any way tuberculosis ascertain if the patient was intimately associated with this member. It is most important to learn all about the grandparents and whether any of them living in the home of the patient ever had chronic bronchitis or other chronic conditions resembling tuberculosis. I should like to emphasize the fact that these socalled cases of chronic bronchitis are our most fruitful source of infection, for many of them are open cases of tuberculosis which may seem apparently healthy with the exception of a slight bronchial trouble noticed usually in the winter and often called a winter cough. If any member of the family has died of tuberculosis it is important to know whether the patient was intimately associated with this person during the time when the disease was active. The age of the patient at time of exposure should be ascertained. It is well to remember that children are more susceptible to infection than adults and it must not be forgotten that although a child may be infected during early life he does not necessarily show symptoms until later, and many infected in childhood never develop clinical disease.

Having carefully studied the family history the next is to get that of the patient. First ascertain what the home conditions were from the earliest childhood, then a history of the childhood diseases, measles and whooping cough being of special importance, and the patient should be most carefully questioned regarding his health following either of these especially if he did not contract them until adult life. Learn what you can of the patient's general health, ascertain if he had any glandular involvement, ever suffered from pleurisy, anal fistula, ischiorectal abscess or discharging ears; these are often forerunners of active pulmonary tuberculosis. Question especially regarding recent diseases the patient may have had, such as frequent colds, grippe, influenza, pneumonia, typhoid fever or any injuries of the chest, surgical operations; also if he made an uneventful recovery. It must not be forgotten that any condition which lowers the patient's resistance

predisposes to tuberculosis, and one should be suspicious of typhoid, pneumonia, or other diseases or surgical operations when a patient makes a slow recovery.

Habit and occupation of patient should be carefully gone into. It is as important to find out conditions under which the patient works and lives as what he does. It is safer for one to do work considered predisposing to tuberculosis and live under the best conditions than it is to do something considered safe and live an irregular life in unfavorable surroundings. Learn if possible if the patient leads a regular life, smokes, chews, drinks, or indulges in other dissipation to excess. The past history of patient being carefully considered, his present illness should be thoroughly studied. Ask him how long it has been since he felt perfectly well rather than how long he has been sick; go back to the beginning and find out all that is possible between that time and the time patient consults you. It may be necessary to go over certain parts of it to help patient recall how his symptoms developed.

Having taken a full and complete history, the next step of importance is to study each symptom or to ascertain what symptoms the patient has developed. There is no symptom pathognomonic of the disease; what one patient complains of first and constantly, the next patient may never have. Tuberculosis often runs the most obscure symptoms, which at times may simulate other diseases. It is therefore necessary that the disease be kept in mind for it is one of the most frequent with which we have to deal and its obscure nature often keeps it in the background until it has become advanced.

If the greatest value is to be obtained from a study of the symptoms it should be done systematically and for this purpose I will group them according to Pottenger under the following headings:

GROUP I	
Toxemia	Digestive disturbances
Malaise	Loss of weight
Lack of endurance	Rapid pulse
Loss of strength	Night sweats
Nervous instability	Fever
Lack of appetite	Anemia
GROUP II	
Reflex origin	Loss of weight
Hoarseness	Circulatory disturbances
Tickling in larynx	Chest and shoulder pains
Cough	Flushing of face
Digestive disturbances	Apparent anemia
GROUP III	
Tuberculosis involvement *per se.*	Spitting of blood
	Pleurisy
Frequent and protracted colds	Sputum
	Fever

Some of these symptoms may fall in more than one group. The symptoms of group one may all be caused by something other than tuberculosis and must be studied with symptoms of groups two and three to be of value. The fact that active tuberculosis may be present without any of the symptoms of group one should not be overlooked.

SYMPTOMS OF GROUP I

The first symptoms of this group, malaise, feeling of being run down, lack of endurance and loss of strength, are common and are frequently the symptoms which first bring the patient to the physician. He does not seem to have the usual amount of energy, does not take the interest in things he did formerly. This is a very significant symptom and especially if the patient states he feels as tired or more so after a night's sleep than he did before retiring. One suffering from tuberculosis usually feels worse when first arising and gradually improves as the day progresses. Nervous instability is a condition often diagnosed as neurasthenia, which like asthma is more often a symptom than a disease and the physician should not be satisfied until a satisfactory cause has been found for the condition.

Digestive disturbances are extremely common in tuberculosis; at times the food is not properly digested; again it may manifest itself in loss of appetite. The patient feels hungry until food is placed before him, then all desire for it vanishes. This is especially true when the patient is tired. It is always wise to watch a patient's appetite closely when first placing him on exercise; if it declines one can be sure he is too active. The amount of exercise should be reduced or discontinued under such a condition. Great care should be used in treatment to see that every precaution is taken to prevent impairing the digestive system, for a good one is the greatest asset to a patient's chance for recovery. Tuberculous patients often have a good appetite, however, when running quite a high temperature which is of value in helping to differentiate it from other diseases when the patient has no appetite with excessive fever. Patients with tuberculosis where the digestive symptoms are pronounced are often treated for stomach trouble without benefit, whereas, when the real cause is ascertained and treated accordingly, satisfactory results are obtained.

Loss of weight is quite common in tuberculosis, but by no means always present. There seems to be a tendency, all too frequent, to think that a patient must be emaciated, otherwise he cannot have the disease. If study of weight is going to be of value, it is necessary to determine patient's greatest weight, present weight and estimated normal weight, for often one weighs himself too infrequently to tell whether he has lost recently.

Occasionally one notices he is steadily losing weight and consults a physician on account of it. The cause should be determined if possible for it is frequently due to tuberculosis.

A pulse higher than normal without a definite reason should be looked upon with suspicion. It is one of the most constant early symptoms in a case of active tuberculosis. It is also of value in prognosis for a patient who runs a persistently high pulse even when other symptoms are improving, has a rather unfavorable outlook.

Night sweat is a symptom quite common and looked upon by the laity as proof of tuberculosis. It is often the thing causing the patient to present himself to the physician for an examination. Sweats are due to toxemia which may be produced by other conditions than tuberculosis; still it should always be looked upon with suspicion until the real cause is ascertained. It is not well to wait until the advent of night sweats to make a diagnosis for it is the sign of excessive toxemia and advanced disease when due to tuberculosis.

Temperature properly taken is of the greatest value in determining active disease. To take the temperature once a day, or when a patient calls at the office, is worse than not taking it at all.

If it is to be of value it should be taken at least four times a day for one week, and the thermometer, regardless of the make, should remain in the mouth for at least five minutes. Cold or hot food or drinks should not have been taken for thirty minutes previous, not should the temperature be taken immediately after the patient has come in out of the cold. Mouth temperatures properly taken are of as great value and as accurate as rectal temperatures. I have frequently seen a patient's temperature reported by conscientious physicians as being below 100° but when properly taken, found to be 102° or higher. It was not because the physician wished to report an incorrect temperature, but because it was taken under the wrong conditions, or the thermometer was not allowed to remain in the mouth sufficiently long to register correctly. A high temperature should not be expected in the early case; one in the afternoon or evening of 99.5°, which can not be explained, should cause one to become suspicious. A temperature decidedly subnormal in the morning is of equal significance.

SYMPTOMS OF GROUP II

The symptoms of this group direct attention to parts other than the lungs. Several of these, digestive disturbances, loss of weight and circulatory changes, have been discussed under Group I and will not be taken up again.

Hoarseness is one of the most common early symptoms and one whose importance is too little valued, and frequently neglected. The condition is treated, at times even by throat specialists, without suspecting that it might be due to tuberculosis. The symptom should always cause one to suspect tuberculosis on account of its frequency. It is usually noticed when the patient is slightly tired or after talking or singing, when the voice has been overtaxed. It may be caused by one of several conditions; first and most common, especially in beginning tuberculosis, is the failure of the patient to approximate the vocal cords on account of reflex nerve condition. Again mucus may be attached to the cords which prevent their free movement and lastly, the larynx may be the seat of a tuberculous process. Do not conclude from this that the disease had its beginning in the larynx, for such is not the case. Within the past month I saw a patient who had been having his throat treated for the past six months, as though the trouble was limited to the area without the condition of the lungs being recognized. After he had grown tired of being treated, without results, he consulted another physician who made a diagnosis of tuberculosis without examination and referred him to a sanatorium. On admission his condition was found to be practically hopeless, not on account of laryngeal involvement but because the lungs were extensively diseased. Six months or more lost treating the larynx as though it was a local condition when the real condition should have been discovered and the proper treatment instituted. The fact that the patient lived as long as he did under such conditions shows that he had a natural resistance and a good chance for recovery had the proper diagnosis been made and treatment instituted.

Cough may be considered a symptom in all cases of pulmonary tuberculosis, for if there are none who do not cough, at least to a slight degree, the number is so small as to be negligible. At times a patient denies having a cough but if carefully questioned he will admit that he has a slight hacking cough, probably noticed the first thing in the morning, although it may be present only on first retiring at night. It may be, and frequently is, first noticed by some member of the family. This hacking cough with or without expectoration should lead one to think of tuberculosis. Any cough lasting more than two or three weeks should arouse suspicion and calls for a careful study and explanation of the cause when not due to tuberculosis. The patient may try to explain that it is due to a tickling in the throat, a little bronchial or catarrhal trouble, etc. The socalled emetic cough is a common symptom and when present should be most valuable in confirming a diagnosis. The patient may cough after eating and vomit although he does not have any sick feeling or discomfort of the stomach; when present one can be reasonably sure it is due to tuberculosis. Pains in the chest and shoulders are as common in active tuberculosis as rigidity of the rectus muscle in appendicitis. One often complains of them thinking he is suffering from rheumatism or he may complain of feeling tired across the shoulders. A careful study of these cases will often reveal early tuberculosis in an active form. A chilly sensation may be complained of which is most common along the spine and described as chills running up and down the back; again one may notice he is more susceptible to changes in the weather than usual.

Flushing of the face is quite common but is more often an indication of advanced or very active disease than a symptom of the early stage. The patient complains of one or both sides of the face feeling hot or flushed. When the process is confined to one lung, the flushing occurs on that side, when present in both lungs it is noticeable on side in which the lung is more extensively or actively involved.

Menstrual irregularities are common in young girls and women suffering from tuberculosis. One patient may complain of the flow being excessive and occurring at too frequent intervals, while the next will complain that the flow is diminished, occurring too infrequently or not at all. The real cause of such conditions should be sought and not explained as being due to chlorosis, anemia or a run down condition, as is too frequently the case. Most of the symptoms described above can be caused by other conditions than tuberculosis; still when carefully studied with those of Group III which will now be described will be found of great value in helping to make a correct diagnosis.

SYMPTOMS OF GROUP III

The symptoms of Group III are due to the lung process per se. The patient complains of contracting one cold after another or he may complain of a cold which may last during practically the whole winter. Many of these patients are suffering from tubercu-

lous bronchitis. If these colds are severe they may be called grippe and sometimes pneumonia. Symptoms such as these always call for a close and careful study of the patient, for when tuberculosis is present it should be detected at this time.

Blood spitting is a symptom which will cause a patient to make his own diagnosis; still physicians sometimes seek to find other causes for it and give an erroneous explanation only to lull patient into a feeling of false security. If any symptom is pathognomonic of tuberculosis it is the spitting of blood. There are causes other than tuberculosis which may provoke blood spitting but they are so rare that it should always be looked upon as being due to this cause until proved conclusively otherwise. It seems absurd to think of a physician offering other reasons for the spitting of blood until a patient has passed beyond the stage when treatment will be of value. A patient who had been having copious hemorrhages once came under my observation after he had been referred by his family physician to a throat specialist who upon examining the throat stated he could see the bleeding point. A few days later the patient had another hemorrhage and again consulted the family physician who assured him he need have no worry as the bleeding came from his throat. It was not until he had a large hemorrhage in the physician's office that a correct diagnosis was made and then only a few weeks before death. Other cases could be mentioned in which the misinterpretation of common and definite symptoms has led to a disastrous ending. If in every case of frank hemorrhage an immediate diagnosis of tuberculosis was made and the proper treatment instituted it would result in fewer mistakes and the saving of many lives.

Pleurisy also holds a more important place in the diagnosis than is usually given it. The majority of pleurisies are tuberculous and should be treated as such. Pleurisy is always serious and should be so considered. Physicians would be surprised if they were to look up the pleurisy patients treated from ten to fifteen years before which apparently made a good recovery; for it would be found that at least half had since died of tuberculosis. In taking the history then ascertain if the patient has ever had pleurisy; if such is the case it should be a great aid in clearing up the diagnosis. History of having had pleurisy is second only to that of blood spitting and when either of them has been present in the past the physician need not have any great fear of making a diagnosis of tuberculosis. Certainly when there are other symptoms which will help confirm it.

If every physician would place more importance on the history and symptoms and use them more extensively more cases of early tuberculosis would be discovered. There is no symptom which is pathognomonic of the disease, but when all are studied together they will prove the most valuable aid we have in the diagnosis of tuberculosis and at a time when it will be of the greatest benefit to the patient and those with whom he comes in contact, as well as satisfaction to the physician..

Subacute Bacterial Endocarditis Complicating Pulmonary Tuberculosis*

BARNET P. STIVELMAN, M.D.
Bedford Hills, N. Y.

It is universally recognized that cardiac affections rarely complicate pulmonary tuberculosis and with the exception of congenital heart lesions the two conditions do not often coexist. As a terminal process endocarditis is not unknown and there are cases on record where the tubercle bacillus itself was found to be the etiological factor. There are, however, very few case reports of subacute bacterial endocarditis complicating a tuberculous pulmonary process. The paucity of such reports is due primarily to the fact that this form of endocarditis has only recently engaged our attention. On the other hand, it is possible that because certain manifestations of pulmonary tuberculosis may give rise to symptoms not unlike those of this malignant cardiac affection, the existence of the latter may often have been overlooked and the ultimate results ascribed to a fatal reactivation of pulmonary tuberculosis. It may, therefore, be of interest to record the case that came under our observation, calling attention at the same time to the salient points in the differential diagnosis.

CASE.—A. P., a Russian tailor, aged twenty-six, entered the sanatorium on September 3, 1918. He stated that he had been in excellent health until three months prior to admission when he had a sudden brisk hemoptysis. Blood streaked sputum continued for several days. After a rest at home for two weeks he returned to work only to have another hemoptysis of eight ounces five days later. At this time patient began to complain of moderate night sweats, cough, expectoration and tiredness, and these were his chief symptoms when first seen.

Physical and röntgenoscopic examinations on admission disclosed a tuberculous involvement of the right upper lobe and left apex. There were no abnormal heart findings. A left internal strabismus was ascribed to a disease in childhood. His sputum contained numerous tubercle bacilli on repeated examination. The urine showed an occasional trace of albumin while the specific gravity ranged between 1008 and 1024.

He had repeated attacks of hemoptysis as well as frequent rises in the afternoon temperature during the first four months of his stay at the sanatorium. The pulse ranged between 76-92 in afebrile periods and between 90-112 when febrile. Cough and expectoration continued unchanged. A severe attack of influenza in the early part of December, 1918,

*From the Bedford Sanatorium for Incipient Tuberculosis, Bedford Hills, N. Y.

confined him to bed for six weeks. At this point patient began to improve in every respect. There was an amelioration in all his symptoms, the temperature remained within normal limits for the rest of his stay at the sanatorium, he gained in weight (fourteen pounds), tubercle bacilli could no longer be found in his sputum and he left the sanatorium with disease apparently arrested in September, 1919.

Second entry March 10, 1923. Patient had been feeling well and working until the latter part of December, 1922, when he had another severe attack of "influenza" which confined him to bed for four weeks. Since then he said he had been running fever which often reached 102° in the afternoon and while his cough and expectoration were comparatively mild he felt he was getting progressively weaker. He complained of pain over the chest and particularly over the sternum while the shortness of breath was the most distressing symptom.

Physical examination disclosed a dyspneic, somewhat emaciated young man with dusky sallow pallor and slightly clubbed fingers. The lung lesion had not appreciably increased. There was evidence of pulmonary emphysema. These findings were corroborated röntgenographically. A systolic murmur best heard at the apex and transmitted to the axilla was noted. No cardiac enlargement could be made out on physical or röntgenological examinations.

While at the sanatorium patient was very toxic. His afternoon temperature ranged between 102-104 with a daily swing of one and a half to three and a half degrees. His pulse was regular and of good quality and ranged between 96 and 120. There was occasional blood streaked sputum. The cough and expectoration were not distressing but the dyspnea grew progressively worse. There was great tenderness over the precordium and particularly over the sternum. His sputum contained tubercle bacilli on one of five examinations, and his urine showed faint traces of albumen on all of five examinations and hyaline and granular casts on one. The specific gravity ranged between 1008 and 1020. Blood pressure 116-84. Blood smears failed to disclose Plasmodium malariæ.

On March 25th the patient complained of a very severe and boring pain in the right hip joint. This was not accompanied by tenderness on pressure or motion. There was slight rigidity of the abdominal muscles on the right side and marked tenderness at the right iliac fossa. The septic temperature continued in spite of therapeutic efforts. The sternal tenderness increased and the dyspnea became much worse. The lung signs were stationary. Pulse ranged between 96 and 120, regular and of fair quality. There was continued loss of weight and strength.

Lumbar puncture revealed clear fluid under moderate pressure with normal cell count. The blood culture on April 16th disclosed an organism of the pneumococcus group.

In addition to the recently noted edema of the legs, marked swelling of the face was seen on May 9th. There was also an extensive petechial eruption on the forehead, face and legs which later spread all over the body. A second blood culture was returned positive for Streptococcus anhemolyticus. He grew progressively weaker and died on the evening of May 15th. Postmortem röntgenographic examination of his chest disclosed a very large, apparently dilated, heart with a moderate hydrothorax on the right. The tuberculous lung process was apparently unchanged.

It is a matter of common knowledge that periodical exacerbations of clinical activity are among the salient features of pulmonary tuberculosis. On the other hand the assumption that most acute toxic symptoms in a tuberculous patient presenting some signs in the lungs can be ascribed to a reactivation of a quiescent lung process has often led to error. Indeed many patients are readmitted to sanatoria on the basis of such assumption when in reality they suffer from a nontuberculous condition not even remotely connected with the respiratory system.

Here is a patient who, three and a half years after his discharge from the sanatorium with his lung lesion in an apparently arrested condition, is readmitted on account of a supposed reactivation of his tuberculous process. From the very start, however, it seems that we were dealing here with a nontuberculous complication. There was no increase in the amount of lung involvement on both physical exploration and röntgenological examination of the chest. Moreover, evidence of a tuberculous complication such as enteritis, meningitis or miliary tuberculosis which could be held accountable for the symptomatology was entirely lacking. Septic foci sufficient to account for the trouble could not be found. Malaria was ruled out by blood examination and therapeutic test and the possibility of the existence of typhoid could be eliminated in view of the long duration of the febrile period. The heart was not enlarged and the systolic murmur heard at the apex and transmitted to the axilla was at first not considered seriously because such murmurs are so often heard in tuberculous patients who, to our best judgment, are not suffering from organic heart disease.

However, when the patient's complaints were gone into more carefully the discovery of the murmur assumed a greater significance. The marked dusky sallow appearance of the patient, the dyspnea in the absence of a progressive lung process or tuberculous complications, the dull aching pain and tenderness over the sternum and the rapidly progressive anemia and asthenia could not in this case be explained on the basis of tuberculosis and pointed to the possibility of septic endocarditis. Finally the occurrence of the sudden sharp, boring and excruciating pain in the region of the right hip a few days after admission suggested an embolus secondary to endocarditis. The heart findings, subsequent course and positive blood cultures determined the true nature of the affection.

SUMMARY

1. Acute nontuberculous conditions in the tuberculous are often mistaken for reactivation of quiescent pulmonary foci.

2. While cardiac affections in the tuberculous are quite infrequent they do occur and should be kept in mind whenever symptoms and signs referable to cardiac disease are elicited.

3. A case of subacute bacterial endocarditis in a tuberculous individual is described. The similarity in the symptomatology of the two diseases and some points in the differential diagnosis are considered.

Croup: Its Differential Diagnosis and Treatment*

GEORGE SWETLOW, M.D.,
Brooklyn, New York

The service of the Kingston Avenue Hospital provides a wealth of information pertinent to the subject of croup. The tremendous importance of the subject is evident since frequently a life hangs in the balance, and a rapid, correct diagnosis determines which way the scales will swing.

It is not a chronic ailment, in which we are interested, where differences of opinion and delay are not of momentary importance, but we are troubled with a hyperacute symptomatology, where at times life is threatened by a few hours' delay.

It has been our experience again and again that patients sent to us with a diagnosis of laryngeal croup have to be reclassified by our service. This difficulty of differential diagnosis is at times troublesome even for those who have been concerned with this problem for years. So it is quite evident that we are dealing with an affection in which a fatal outcome is often immediate. Its recognition is extremely difficult, offering great embarrassment to those who see few such cases and many perplexities to the experienced.

In considering the various diseases which give rise to the classical signs of laryngeal stenosis, I wish to confine myself particularly to those the onset of which is sudden and the course rapid. We are not here concerned with chronic stenosis as seen in the presence of malignant glands of the neck, epithelioma of the esophagus, enlarged thyroid, or mediastinal tumor. In approaching a case in which we are to determine the presence or absence of laryngeal croup, we observe that in the greater percentage of cases little difficulty is encountered. It is the smaller group of cases that especially interests us.

Before entering into the discussion of the individual diseases, that are frequently confounded with true laryngeal croup, I wish to give a brief résumé of the important phases of this serious malady.

This picture will be used as a basis in the differentiation. It is important to note that, although the laryngeal involvement is often primary, nevertheless in the majority of cases it is secondary to nasal, faucial or tracheobronchial diphtheria. We can divide the drama into three acts: 1. Stage of invasion. 2. Stage of spasm. 3. Stage of asphyxia.

In the stage of invasion it is not uncommon to have the child running about for a day or two with an angina or a purulent nasal discharge, when suddenly hoarseness and difficulty in breathing supervene. It is both interesting and of significant value to observe at this stage, whether the croup is primary or secondary, that a negative culture is often obtained. Slowly and persistently the child progresses to the spasmodic or exudative stage. In the early part of this period, a pseudomembrane may appear and spread so quickly, that within twenty-four hours symptoms of marked stenosis may become evident. The first stage in the scene is slight hoarseness, which may progress to aphonia. We must not place too much reliance upon this phenomenon, for, as has been pointed out by the late Dr. Lynah, many of the laryngeal croup cases may present a normal or slightly altered voice, depending on the location of the membrane in the larynx. The constant irritation by the pseudomembrane and toxin upon the superior laryngeal nerve brings on a cough, which may even at times become paroxysmal in character. As several hours elapse, the respiration becomes noisy and harsh. The inspiratory phase of the respiratory murmur becomes prolonged. The expiratory phase is harsh and a definite pause separates the two phases. Although the inspiration becomes prolonged, the amount of air entering the lungs becomes markedly diminished. The train of symptoms progresses until we get the dreaded picture of stenosis. All the accessory muscles of respiration, the scaleni, intercostals and diaphragm, are brought actively into play. It is of value and interest to mark, that in spite of the dyspnea, the respiration rate is about normal, being in the neighborhood of 18-20 a minute. On direct examination of the larynx by means of the laryngoscope, we find that the vocal cords are covered by a membrane and are practically in contact with one another. In untreated cases in which antitoxin has not been administered, the stage lasts from twenty-four hours to one week. The climax is that of asphyxia. Here we have a combination rôle of both stenosis and toxicity. The respirations become more and more rapid, irregularity increases, and violent irregular contractions of the accessory muscles of respiration are necessitated. The pulse, poor in quality, begins to drop several beats with each inspiration, foretelling that the end is not far distant. The face and lips become livid and a cold perspiration breaks out. Death is due to carbonic acid poisoning, bronchopneumonia or cardiac dilatation. A fatal termination is seen in ninety-five per cent. to ninety-eight per cent. of all untreated cases. I have described the course of the common variety of laryngeal croup, omitting the phlegmonous and septic forms.

The most frequent condition that is met to confound us, is the socalled false croup, often known as spasmodic croup or laryngismus stridulus. The latter is the name selected for the severe form of the ailment, particularly seen in weak, debilitated or rachitic children. At times this may even progress unto death. Here all the acuteness, intelligence and experience of the observer are severely taxed. Not only is the diagnosis important as to prognosis but even more so as to treatment. What are the differential points? What are the characteristics that indicate a diagnosis? I will summarize them in a didactic manner, feeling that only in this way will an indelible impression be made. It is important to comprehend, that in a child the larynx is relatively smaller in its relation to the general bodily development than are any of the other organs, so that the least amount of swelling of the mucous membrane necessarily causes an encroachment on the laryngeal

*From the Kingston Avenue Hospital of the Department of Health, New York City.

lumen. The glottis is predominantly involved because of the particularly loose attachment of its mucous membrane.

Due to adenoidal infection, constant dripping of secretions into the pharynx and into the larynx keeps up a continuous irritation with resulting involvement of the glottis and secondary precipitation of spasms. The swelling of the mucous membrane, especially near the vocal cords, is quite frequently noticed with the laryngoscope. In making inquiries concerning the child's history one can usually elicit the information that, as out of a clear sky, hoarseness and croupy signs appear. The attacks usually come on during the night. But this by no means is the invariable rule. At times there is no history of an inflammatory process existing elsewhere, but as a thunderbolt, the child suddenly awakens during the night with a characteristic croupy cough and dyspnea. Once more let me repeat, that just as in laryngeal croup, the voice may or may not be altered at all. In the greater proportion of cases, as night approaches, the voice becomes raspy and metallic in character, often accompanied by a short cough, and within several hours the typical spasmodic picture is arrived at. Sometimes before the actual spasm makes itself manifest, we note physically an inspiratory dyspnea and a peculiar stridor, which may go on to marked cyanosis or even necessitate immediate intubation. In between spasms little or no hoarseness is heard and the child's color and pulse are again in a good physiological state. There may be several such attacks, especially during the night, each lasting from a few minutes to several hours, terminating abruptly. I wish to recapitulate in a concise manner the differential points in favor of false croup.

1. There may be a short history of inflammation elsewhere, characterized by a nasal discharge or a slight cough.
2. The attacks are usually seen during the night.
3. The onset is sudden and the termination is abrupt.
4. There is usually no fever.
5. The symptoms are not as progressive and as persistent as in diphtheria.
6. The color between spasms is good.
7. The cough is metallic and not that of croup.
8. There may be several such similar attacks during a single night.
9. Unlike diphtheritic croup, the spasm rarely progresses to intubation.
10. There is no membrane on the tonsils, throat or in the nose.
11. There is an absence of glandular enlargement, i. e., submaxillary and cervical.

Many cases often come under our care, which are classified purely as catarrhal laryngitis showing most of the symptoms noted, but instead of no or little temperature, we have a fairly high level, reaching as high as 103-105° F. It is often this catarrhal condition, that gives rise to the spasmodic attacks and general symptomatology noted in the observations on false croup.

In completing the discussion of false croup, we are now ready to consider conditions, which are not as frequent but nevertheless of great importance. The consideration of aspirated bodies has in the past shown itself to be of such momentous concern, that I will review a case which was seen in the Kingston Avenue Hospital several years ago.

Case.—A child seven years of age was admitted to the Willard Parker Hospital with the following symptoms: croupy cough, marked retraction, a temperature of 103° F., and a pulse of 140. A diagnosis of croup was made and antitoxin was administered. The child was ill for several days and was finally transferred to the Kingston Avenue Hospital. While here the resident physician, Dr. Cannon, in making rounds, noticed a swelling in the middle of the larynx. A diagnosis of perilaryngeal abscess was made, and on opening the abscess, he noticed a foreign, bright body, which fell deeper into a bronchus before he could grasp it. Dr. Lynah by means of a bronchoscope removed a safety pin.

I will describe briefly the average clinical picture of a child, who has aspirated a foreign body. A perfectly healthy child, while playing, is suddenly and abruptly seized with an attack of coughing, dyspnea and cyanosis. The dyspnea may be so severe and acute, that death may ensue immediately. However after the initial attack of coughing, many of the patients gradually and persistently progress to greater and greater degrees of dyspnea and cyanosis. Physically the findings depend on the location of the obstruction. If the impediment is in the larynx, the air hunger is exceedingly urgent and causes grave concern. The color of the face and lips may be livid. The head is thrown slightly back. The child is extremely restless. The excursions of the thyroid cartilage are extensive. The voice is not altered unless the foreign body has caused an edema of the true vocal cords. The dyspnea is inspiratory in type, and the loss of aeration is equal in both lungs. A quite different picture is seen if the obstruction is located below the larynx, especially when a bronchus alone is occluded. Here the patient is usually quiet. The color may be of various shades of cyanosis. The voice remains unaltered and the excursions of the thyroid cartilage are not as extensive as they are in the higher form of obstruction. The neck is slightly flexed and the trunk is somewhat bent forward. The air hunger is not urgent enough to give immediate concern. The percussion note on the obstructed side is that of a high pitched impaired note varying from dullness to flatness. The breath sounds are absent or greatly diminished. The expiratory phase of the respiratory murmur is greatly prolonged. Bronchophony and pectoriloquy are greatly diminished. The x ray plate shows on the side of the obstruction that there is less absorption of the rays than is observed on the unaffected side, because of the imprisonment of air. The foreign body may or may not be been. What shall our attitude be in such cases?

1. The sudden occurrence of dyspnea in a child, particularly coming on during the day, should suggest the idea of a possible foreign body.
2. The sudden onset, occurring within a few seconds, in a perfectly healthy child should again arouse a similar suspicion.
3. The appearance of a slowly progressive dyspnea should also put the observer on his guard.

In the opinion of Dr. Lynah, a bronchoscopic examination for foreign body is indicated in all cases exhibiting a sudden appearance of dyspnea in an

otherwise healthy child, in all cases exhibiting a slowly progressive dyspnea, and in all cases which occur in the day and whose etiology is unknown.

Great difficulty is being experienced in differentiating laryngeal croup from influenzal croup. A similar difficulty in differential diagnosis was found in the 1919 influenza epidemic. In the 1919 influenza epidemic cases were observed by Dr. Regan and the late Dr. Lynah, that were sent to the Kingston Avenue Hospital with a diagnosis of laryngeal diphtheria, but on further investigation failed to show the ordinary course of croup. The immediate characteristics that suggested that another ailment was being encountered, were the facts, that the symptom complex was occurring in an epidemic, that the cases did not respond to massive doses of antitoxin, that none of the patients showed paralysis, that there was no membrane in the nose, throat and larynx. With the foregoing facts in mind as indications, routine examinations of the larynx were instituted with the following findings: The larynx failed to show the presence of a membrane, and instead it was fiery red in color. The ventricular bands and vocal cords were edematous and a stippling of whitish spots was seen on the deep red background. This picture was particularly noticed in the severe streptococcic forms. In this type the edema was supraglottal and interfered with the respirations. In other cases similar pathology was observed to be subglottal and tracheal. Few patients showed the involvement of the bronchi and in others the entire passageway was affected. The symptoms began with a chill, dry cough, vomiting, aches in the lumbar muscles and extremities, and increased secretions from the nose and the conjunctiva. Within two to ten days from the onset, croupy symptoms began to appear, progressing even unto laryngeal stenosis. In mild forms the hoarseness and croupy cough cleared up, but in the severe types, with or without pneumonia the process often went on to stenosis. Even as early as twenty-four hours from the onset, hoarseness and croupy cough developed in some of the cases. Within a few hours difficulty in breathing became evident.

From here on if the case progressed, all the scenes depicted in laryngeal diphtheria were reenacted. If a pneumonia was present, we found that the aeration was diminished and a moderate number of musical râles was heard. The throat was congested but there was seen no purulent discharge from the nose. The mouth, tongue and throat were red, dry and glossy. There was no enlargement of the glands. On culturing the secretions from the nose and throat, Pfeiffer's bacillus was most frequently found with the micrococcus catarrhalis and pneumococcus a close second. Therefore to differentiate laryngeal diphtheria from influenza croup, a thorough history as to the onset, particularly as to nasal and conjunctival discharges, headaches, chills, pains in the lumbar as well as the muscles of the extremities are carefully to be observed. A rigid physical examination and history of exposure in the presence of an epidemic must be obained. The absence of a membrane in the throat and he presence of a dry, red glossy mouth, tongue and hroat should be observed. A laryngoscopic examnation should finally complete the investigation. All his should be done to clinch the diagnosis of inluenzal croup. We urge care in this differential, for so much depends upon this. Intubation usually does not relieve, but on the contrary increases the congestion in the larynx and as a result the efforts of inspiration are more seriously impeded. The croup kettle, atropine, morphine, adrenalin, flax seed poultices to the neck and mustard paste to the chest in cases complicated by pneumonia, are apparently of great value.

There should be no difficulty in differentiating croup from retropharyngeal abscess. But due to the failure of examining the throat with the finger or due to oversight, patients have been admitted to the hospital deathly sick, in whom treatment along lines of diphtheria had been instituted. Usually following some infectious process in the nasopharynx, the lymphatics draining into the retropharyngeal lymph glands infect them. These glands become larger and larger and as a result the pharyngeal wall is pushed forward. The swelling is usually lateral to the median line, for the glands are situated there. The clinical history is that of a child usually under one year of age, although cases are seen at three, who has been ill for several days with a nasopharyngitis. Suddenly difficulty in swallowing and at times even regurgitation through the nose occur. Along with this respirations are impeded. There is often heard a gurgling, spluttering sound as though there is mucus in the larynx. This is not to be confused with stridor. The respiration through the nose becomes obstructed and snoring results. As the case progresses, pressure on the larynx ensues and dyspnea begins. Hoarseness is not heard but the voice takes on a nasal quality. The head is thrown back, usually to one side, and the mouth is held wide open. Physically one can see a mass, lateral to the median line, pushing the retropharynx forward. On palpation the swelling is confirmed as located retropharyngeal. Treatment should be surgical only.

Although it is conceded that the bulbar form of polioencephalomyelitis is of infrequent occurrence, it nevertheless is one of the affections that must be differentiated from laryngeal croup. Great difficulty is often experienced in making the differential diagnosis.

Early in the disease there is an irritation of the recurrent laryngeal nerve. This is manifested by an abductor paralysis of the vocal cords. There is observed a stridulous inspiratory dyspnea due to the spasm of the glottis. When the nerve finally passes from the irritative to the destructive stage, we find that the symptoms then depend upon an abductor paralysis. The dyspnea, inspiratory in nature, becomes a matter of exceedingly grave concern. If a complete examination is made, the findings of a basal nuclear involvement of the cranial nerves will be found. The fifth, seventh, ninth, eleventh, twelfth and frequently the second and third nerves are implicated. These findings together with examination of the cerebral spinal fluid definitely and conclusively make the differentiation.

Often complicating scarlet fever, measles or whooping cough there are seen symptoms, which clearly point to impairment of respiration. But, keeping the symptoms of these particular diseases in mind, there ought to be no difficulty in explaining the symptoms and prescribing treatment adequate for each of the diseases in question.

SUMMARY

1. That there are many ailments that disguise themselves as croup.

2. Before making a diagnosis of laryngeal croup, it is necessary to carry out a complete and thorough physical examination in order to rule out stimulators.

3. If there is any doubt in diagnosis as to the presence of diphtheria even if the symptoms are not of a stenotic type, antitoxin should be administered. There can result no injury from such a procedure.

A New Technic for Investigating Maxillary Sinuses by X Rays

HERMAN BESSER, M.D.,
New York

The problem of obtaining x ray pictures of clear maxillary sinuses without showing superimposed tissue and bony structure has occasioned a search for a better technic. As a result of my research work along these lines, I have devised a new technic which gives a clear and truthful x ray picture of the maxillary sinuses.

The usual technic for maxillary sinuses consists of anteroposterior views in which the patient is placed in position as follows:

The head is placed on a horizontal plane with the nose and chin in contact with the plate. The cone of the diaphragm is centred on the same plane over the region of the occiput. The object of this position is to throw the malar bones out of the field of the sinuses. Likewise the mastoid regions are thrown upwards. The maxillary sinuses are seen on either side of the face at radiolucent areas but these radiolucent areas are composed of shadows of the posterior portion of the skull as well as shadows of the malar bones and intervening tissues. Even when great care is exercised in radiographing the sinuses by this technic heterogeneous shadows cannot be excluded and tend to give a hazy appearance to the antra.

An ideal representation of the maxillary sinuses is one in which the superimposed bony structure can be excluded from the picture. Because of the bilateral shape of the head, lateral and anteroposterior views cannot give this. The following technic which I worked out focuses the rays upon the head placed in a new position and gives a clear picture of each maxillary sinus with no superimposed bony structure in the field.

The patient is placed on his back with the head tilted backwards, at an angle of 25°. The side to be x rayed is placed on the plate. The tube is tilted to an angle of sixty degrees and the cone is brought downwards and as near to the uppermost mandible as possible.

This position gives a direct line from the tube to the maxillary sinus with a minimum amount of soft tissue and with no superimposed bony structure intervening.

The accompanying cut shows the maxillary sinus appearing as a clear oval cavity. There is no evidence of any bony structure of the face or occiput visible. Note that the superior and inferior molars on the same side are seen in their normal positions, while the molars on the other side are entirely thrown out of the field. The clarity or haziness of the sinuses can be easily discerned by one familiar with reading röntgenograms. The advantage of this technic is apparent by a comparison of a cut representing the usual method of sinus investigation.

It should be added also that the maxillary sinus on the opposite side should always be radiographed with the same technic for comparative study of the suspected side.

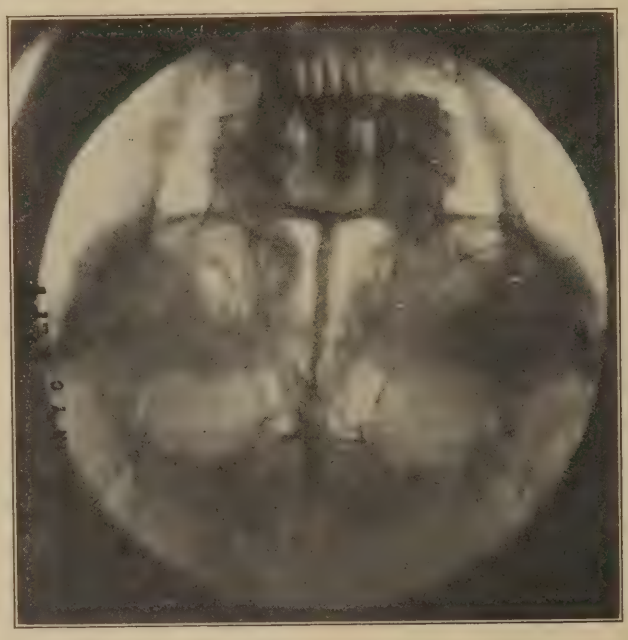

Fig. 1.—Old technic.

Fig. 2.—New technic.

Treatment of Tonsillar Hemorrhage*

HENRY H. BEINFIELD, M.D.,
Brooklyn, N. Y.

Bleeding following tonsillectomy is not given the serious consideration it deserves. This operation although comparatively safe is not unattended with dangers and may result in serious hemorrhage unless one is properly prepared to meet the emergency. Tonsillar hemorrhage occurs more frequently than is usually supposed, especially now when so many tonsillectomies are performed. Tonsillectomy is a major operation and should be regarded as such, just as much as a hernia or appendectomy. The blood supply to tonsil and neighboring structures is rich.

The causes of tonsillar hemorrhage are usually due to anomalous bloodvessels or to the removal of some of the soft parts, such as the pillars or deep muscle tissue. Hemophilia plays an important part as a causative factor. Bleeding frequently is traced to the leaving of a small piece of tonsillar tissue in the fossa.

Bleeding may be primary, coming on at the time of operation and is the most frequent form, or secondary, occurring from two to ten days after operation. Secondary hemorrhage often results from the tearing away of the slough or necrotic membrane which forms after a tonsillectomy, thus exposing a superficial bloodvessel or as sometimes happens during sudden laughter or screaming the slough becomes loosened from its base, thus disturbing the clot and opening the thrombosed vessel or by disturbing the granulation tissue which forms and helps to fill in and heal the tonsillar fossa.

Tonsillar bleeding may be classified according to degree as follows: Slight when the amount of blood lost does not exceed three to four ounces; moderate when it does not exceed ten to twelve ounces and severe when over twelve ounces.

You will find that sharp cutting instruments will give you more bleeding than dull instruments which crush the vessel. The method used is a matter of personal preference and does not alter the possibility of hemorrhage, every method being subject to the same risks of bleeding. Under local anesthesia it is possible to perform a bloodless tonsillectomy by properly preparing the field of operation, whereas under general anesthesia this is not always possible.

Several remedies have been recommended to improve the coagulability of the blood, prior to operation; as an additional safeguard against hemorrhage, calcium lactate and calcium chloride are examples. It is questionable just how much good they really do. Thromboplastin and hemoplastin given hypodermatically about one hour before tonsillectomy tend to lessen the bleeding which comes from the capillaries. As an added precaution, every patient should have a blood coagulation test made.

In those cases which I classified as slight bleeding, the bleeding will be found to be due to a general oozing which would follow from any ordinary incision. For these cases slight pressure in the tonsillar fossa low down and against the anterior pillar pressing toward the angle of the jaw, with a plain sponge, will often control it in a few minutes. Be sure the bleeding from one tonsil is controlled before removing the other.

In cases of moderate bleeding, pressure may also be used. Where this fails the sponge may be saturated with medicaments such as peroxide of hydrogen, adrenalin, tannic acid, thromboplastin and bismuth subnitrate.

Where the bleeding is severe and the blood is seen to be spurting from a vessel, steps should immediately be taken to control this, just as in any surgical operation. This is done by promptly clamping the bleeding point and ligating it, without even wasting time trying any of the foregoing simpler nonsurgical methods, as a great deal of time and blood will be lost. When the vessels are properly ligated one can leave the patient in safety. Sometimes just clamping the bleeding vessel and crushing it without ligation will control the hemorrhage, but this method is by no means safe.

One frequently encounters a case where the bleeding does not come from any definite vessel, but there is a steady constant oozing. This usually occurs as a result of the soft parts surrounding the tonsil having been included in the tonsillectomy, removing muscle tissue, pillars or parts of the soft palate. For these cases, if the patient is in good condition, I should try the simpler methods first but, on the other hand, when you are called to see a patient who has lost considerable blood, you must act more radically to control the bleeding. This is best done by suturing the tonsillar pillars together over a gauze sponge, which is left in position for thirty-six to forty-eight hours when it is carefully removed.

In conclusion, I wish to state that a great deal of trouble and anxiety can be prevented by: 1. Ascertaining the general condition of the patient and his susceptibility to bleeding, by doing a blood coagulation test. 2. Selecting the proper instruments. 3. Being careful not to leave stumps at base of tonsil. 4. Making sure that one tonsillar fossa is absolutely dry and not bleeding before attempting the removal of the second tonsil. 5. Last and most important, that a tonsillectomy should not be considered finished unless all oozing and bleeding has been visibly controlled while the patient is still on the operating table.

The Convalescent Treatment of Lung Abscess

HARRY KLAPPER, M.D.,
White Plains, N. Y.

In this brief paper it is our object to report an experience with seventy-eight consecutive cases of lung abscess convalesced at the Burke Foundation country home during the past seven years. When the institution first opened a somewhat hopeless view was given of lung abscess in our field, but methods of diagnosis and treatment have gradually improved.

Recent articles by Lockwood, Hedbloom, Bettman, Meyer and others have gone into much detail, and especially in the first named will we find this disease fully discussed. The recent writers discuss the treatment—medical, surgical or otherwise, but the long aftercare period between the time of discharge from hospital and the resumption of occupation, or the relapse and return to treatment, is almost entirely ignored. In a personal letter from Lockwood he recommends long aftercare (one to two years) in a dry, sunny climate, but prefers not to move the patient too far from the zone in which he intends to make his livelihood.

How are any, excepting the wealthy, to receive such care? There is nowhere provision for the majority. The average patient is treated in hospital and when ready for the long term recuperation is sent to relatives or friends, or to a boarding house, continuing for a time the usual desultory dispensary treatment. Few enter convalescent homes, which at present are not well equipped to take care of these cases properly and over long periods. In most instances the patient soon returns to the city in very poor condition, without funds and unable to work. Frequently relapse or intercurrent disease overtakes him and he is returned to hospital. Here he soon becomes ambulatory, is discharged, and the cycle starts again, making what Frankel has aptly called "a class of people who are half cured."

Right employment and skilled aftercare are most important in consummating cure in lung abscess, or in obtaining reasonable extensions of their handicapped careers. These patients often look so well after country recuperation that too strenuous occupation is insisted upon, with disastrous relapsing. Even the trying ordeal of job seeking should be avoided, and advance arrangements made for right employment, environment and social regime. In this phase the cooperation of Social Service and the Employment Bureau for the Handicapped have proved invaluable in the New York district.

The following outline of the daily routine at the Burke Foundation Home (varied somewhat to fit patients' conditions)will indicate the main restorative elements in this country rest-play-work therapy: Rise at 6:30, walk or sit out, breakfast at 7:30, bedmaking and light cottage duties, morning papers, smoke (but little restricted), library, walks, games indoors and out, light gymnastics for some, milk at 10, prescribed occupation therapy 10:30 to 11:30 (mainly outside), rest or play till dinner at 12:30; rest hour on bed 1 to 2; afternoon free, but with directed mild outdoor games and various walks, recreations and occupations; supper at 5, evening dances and entertainments (outdoors seven months of year), lights out at 9 p. m. Extra milk and olive oil are often prescribed for these patients The diet (fully studied in a special report now available) is moderate in meat but ample and balanced. The lung abscess patients are more rested, given lighter occupations and recreations, urged to walk and sit outdoors, and generally watched more closely and held for longer stay than others.

In this series of seventy-eight cases, only forty-one could be traced over a period of six years, through followup workers.

AGE TABLE

Under 20	6	7.6 per cent.
20 to 40	53	67.8 per cent.
40 to 60	17	21.7 per cent.
Over 60	2	2.5 per cent.

Over two thirds were between the ages of twenty and forty, in the socalled prime of life.

Of the seventy-eight patients, twenty-five received operative treatment, forty-eight medical treatment, and five treatment by bronchoscope.

The number readmitted to this one institution gives some indication of the tendency to recurrence and the need of more prolonged treatment and observation. Seventeen were readmitted once. Ten were sent out twice or more.

End results in this dread disease have heretofore been little reported upon. The following table is instructive:

FOLLOW-UP RECORDS

Reported fully cured	21	51.2 per cent.	
improved	13	31.9 per cent.	
sick	4	9.8 per cent.	
died	3	7.1 per cent.	
Total follow-up records received			41
In full occupation	20	48.8 per cent.	
In part time occupation	8	19.5 per cent.	
Improved, no occupation yet	6	14.6 per cent.	
Unclassified	7	17 per cent.	

This eighty-three per cent. reported cured or improved gives a decidedly more encouraging picture than is usually presented. It is thought, after full consideration, that the thirty-seven cases which could not be followed long or accurately would not differ materially from the above in terminal conditions.

GAIN IN WEIGHT

Number who gained in weight	62	79.4 per cent.
Number who lost	13	16.7 per cent.
Number remaining stationary	3	3.7 per cent.
Total weight gain	470 lbs.	
Total weight loss	31 lbs.	
Average weight gain	5.6 lbs.	

Many patients come full weight and tissue soft from forced feeding and inaction, and a slight weight loss may go with an excellent convalescent result.

*Note: A complete bibliography will be published in the author's reprints.

PERIOD OF COUNTRY CONVALESCENCE

	Average Length of Stay	In Full Occupation (Follow Record)	Part Occupation	Improved No Occupation Yet	Sick	Died	Gained Weight
All cases	31 days	48.8	19.5	14	9.8	7	5.6
Long stayers (over 20 days)	37 days	64.5	19.3	12.9	3.2	0	6

It is agreed that the length of their country resilence should run into months; but various home nd economic conditions interfere with this ideal. Ve must then depend upon skilled aftercare and lirection following the patient for a long time hrough home and industrial conditions.

The pressing need now is for the establishment of special new type of lung convalescent institution. Ve may quote from Sinclair: "Experience in genral convalescence soon shows that certain kinds of espiratory disease continue to "fall between" all resent relief efforts. They may be called the lung orderliners. Lung abscess, the pretuberculous, the rrested tuberculous, some cases of chronic bronhitis, bronchiectasis and asthma, reoperative and rippling empyemas, fibrosis, and the severer pleuisies. Many of these persons markedly retard the ecoveries of those about them because of disturbng cough, odor, night distresses, contagion fears, tc. They tend to create unfavorable atmosphere in he mixed grouping. Furthermore, they are freuently not thoroughly diagnosed, make little progess, may actually prove contagious, and are really misplaced—or unplaced. In this new institution a moderate amount of "lung atmosphere" would be accepted and well managed, with no "san" stigma following. Diagnoses could be expertly confirmed and patients rightly replaced, special treatments and research carried out, preventive recuperations fully consummated, etc. The lung abscess perhaps best typifies this entire class. This condition is being increasingly diagnosed with the newer procedures, is treated in the hospitals with growing hopefulness, and then essentially falls by the wayside on discharge. Thirty to fifty beds, taking patients of both sexes from fifteen years upwards is suggested scope of the place at beginning. The average stay would be fairly long, and costs a little higher than standard convalescence."

SUMMARY

Since the completion of this study increasing numbers of lung abscess patients have been here convalesced, and with steadily improving end results. More reports by others from the years long follow-up of this disease are much to be desired.

Failure to convalesce fully, and then to readjust these patients in suitable occupations and modes of living is causing too frequent relapse, waste of effort and reproach to the medical profession.

It is proved that standard country convalescent homes can assist greatly in the cure or amelioration of this disease. There is, however, sore need for special respiratory country institutions functioning between these and the tuberculosis sanatoria.

Incidence of the Kahn Flocculation Reaction in Tuberculosis*

ROBERT A. KILDUFFE, M.D.
Los Angeles, Cal.

Among the numerous serum floccule forming rections devised for the serological diagnosis of syphis is that proposed by Kahn (1).

A factor of importance in the evaluation of any iboratory procedure is the determination of the inidence of its occurrence, not only in the particular ondition for which it was devised, but also in other onditions; in other words, are false positive rections obtained in other conditions, and, if so, how ften?

Tuberculosis is one of the numerous conditions hich have been reported, in the older literature, as iving a positive complement fixation reaction with yphilitic antigens. Though this has since been iown to be incorrect, it seemed of possible interest uring the course of an investigation of complement xation reactions in tuberculosis the results of which ill be published elsewhere, to apply the Kahn test the sera under observation.

Because of the numerous, though perhaps imortant, modifications which have followed the origal publication of this test, it is essential to note iat the tests herewith reported were made in accordance with the technic of the original publication and with anitgens kindly furnished by Dr. R. L. Kahn.

The Kahn test was made upon seventy sera from cases of known tuberculosis in varying stages of activity. The sera were never older than forty-eight hours, were all clear, and all inactivated for fifteen minutes at 55° C.

Completely negative results were obtained with all but four of the sera tested.

In two of the cases giving a positive Kahn reaction, both the history and the complement fixation test for syphilis by Kolmer's quantitative method were negative.

In the other two cases in which the Kahn test was positive the Wassermann test by the quantitative method was also positive. One case presented a secondary rash and the other had a history of an initial lesion thirty-five years before.

The series is, of course, too small for any definite conclusions but suffices to show that the Kahn reaction does not appear to occur in tuberculosis with undue frequency.

Angioma of the Larynx*

GEORGE D. WOLF, M.D.,
New York

This case is reported because of the rarity of this particular neoplasm as found in the larynx. John Phillip and H. O. Ruh, in reporting a case in 1913, traced twenty-six cases in the world literature. Emil Mayer reported a case in 1916, and after careful search he brought up the total number of cases reported to that date to forty-one. New and Clark, in 1919, reported three cases from the Mayo Clinic; and after reviewing all the previous cases to that date, brought up the total to fifty-five. Irwin Moore read a paper at the Second Annual Summer Congress of the Section of Laryngology, Royal Society of Medicine, on June 25, 1920, in which he offered a critical review and a general treatise on the subject of angiomata of the larynx, and in that paper he traced seventy-three cases which included two or three of a doubtful character where the diagnosis was not conclusively proved. Since that date the following two cases have been found in the literature. The first, a case of hemangioma of the larynx, was reported by T. H. Sweetser.

CASE I.—The patient was a baby boy who was born prematurely at eight months and died at the age of sixty-two days. Up to the age of nine days the boy appeared to be normal; after this he had a series of attacks of cyanosis with poor respiration,

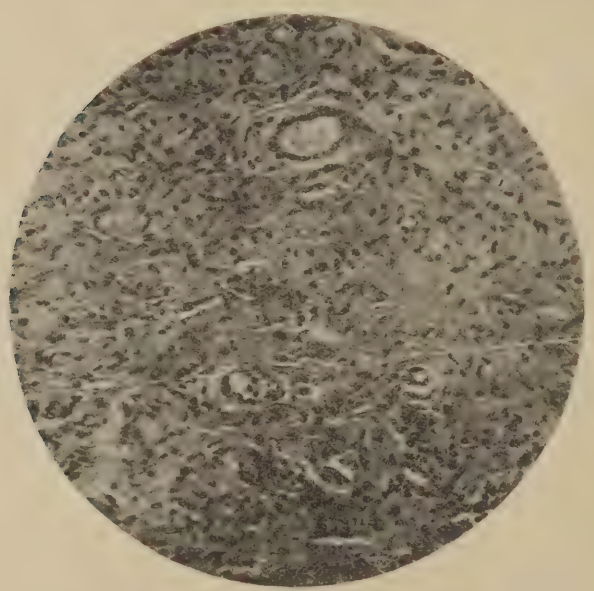

FIG. 2.—Photomicrograph of tumor showing numerous thin walled bloodvessels.

tachycardia and cardiac arrhythmia. Administration of oxygen relieved the condition. Milk was regurgitated, deeply colored red. From that time improvement was continuous and he left the hospital gaining in weight and nursing from the breast regularly. Five days before death the child had difficulty in breathing which was thought to be an asthmatic attack, and later a diagnosis of laryngeal diphtheria was made. Intubation was attempted without success. On autopsy, the hemangioma was found which occupied the entire circumference of the larynx, with the exception of a narrow zone, at the posterior commissure.

J. B. Cavenagh reported a case as follows:

CASE II.—Male, aged thirty-two years, had suffered from hoarseness, with momentary periods of aphonia, since 1916. A diagnosis of tuberculosis had been made and the patient sent to a sanatorium for several months. He was seen by Dr. Cavenagh in 1921 and on examination a pedunculated tumor, the size of a small bean, was found situated over the anterior commissure which prevented the proper approximation of the cords. The growth was removed by the direct method with good results and the microscopic examination showed it to be a hemangioma. Hence, as far as known, the number of cases reported totals seventy-six.

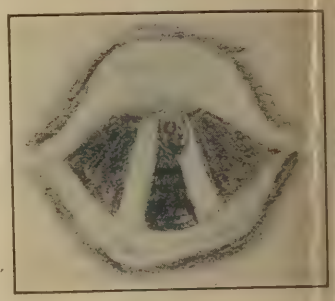

FIG. 1.—Showing larynx congested and ventricular bands edematous.

CASE III.—X. Y., aged forty-two, born in Russia, male, merchant by occupation, married eleven years, no children. Father and mother were alive and well; one sister died at the age of twenty-six of tuberculosis; one brother died at the age of thirty-eight from cerebral hemorrhage; one sister died at forty from nephritis; one brother alive and well.

The patient had had measles and smallpox at the age of four. His habits were good. Fourteen years ago he had had a cough, with loss of weight and night sweats, and the condition was at that time diagnosed as a double apical involvement. There were no pulmonary hemorrhages at that time. Sputum was positive for tubercle bacilli for five months. No history of any venereal diseases. Three years ago he had a lame right leg which was ascribed by the attending physician as due to ulcerative enteritis (?) (Abrams's method). After this cleared up the serological examination was four plus positive for lues, which, after intensive specific treatment became negative and has so remained until the present date. The patient was also subject for a long time to frequent colds in the head and occasional attacks of sore throat.

Present complaint dates back to July, 1922, four months previous to the date when he was first seen. The patient suddenly expectorated about a tablespoonful of bright red blood. He believed this to come from the throat. The same recurred a week later following bathing in the ocean. His chest was examined at the time by the attending physician who could not find in the chest the reason for the hemorrhages. From then on the patient had hemop-

*Case presented before the Section of Rhinology and Larynology of the New York Academy of Medicine, December 27, 1922.

tysis every second or third day, varying in intensity, but never of any alarming degree, up to the time of the examination.

On examination of the larynx, on November 13, 1922, on high phonation, there was found a small sessile neoplasm, larger than a hempseed, somewhat elongated, the surface being nodular, bluish red in color, resembling a raspberry in appearance. This neoplasm was situated at the anterior commissure covering about one fourth of the anterior portion of the left vocal cord. On phonation it prevented full adduction of the vocal cords. The larynx as a whole was congested and the ventricular bands slightly edematous (Fig. 1). On November 17, 1922, a piece of the neoplasm was removed and submitted to Dr. E. P. Bernstein for examination who reported as follows: The surface epithelium was found to be normal. The submucosa was occupied by the loose connective tissue network in which were a few small round cells and numerous thin walled bloodvessels. There was no evidence of malignancy or tuberculosis. A diagnosis of angioma was made (Fig. 2).

There was moderately active bleeding after this procedure, which was easily controlled by the galvanocautery. As a result of this the hemoptysis ceased to recur. On November 17th, after having ascertained the nature of the neoplasm, the galvanocautery was reapplied.

The subject of angioma of the larynx has been so well covered by men who previously reported this condition, particularly by New and Clark, Irwin Moore and Blumenfeld, that to go into it again would be mere repetition. Those interested in the subject are referred to the two last named authors whose articles are most illuminating. Briefly speaking, one can say that the etiology of this condition is believed to be congenital in character, even though local manifestations do not occur until later in life.

With a history of hoarseness, repeated hemorrhages with no accountable source, and the presence of a neoplasm anywhere in the larynx, one must always bear in mind the possibility of an angioma. No standard treatment is advised, and one must judge each case on its own merits. When the tumor is large, the removal of a specimen, even for diagnostic purposes, is fraught with a considerable amount of danger, and deaths have been reported. Hence, in these cases, one has to choose between expectant treatment, laryngofissure or radium. In small neoplasms, similar to the one here described, galvanocautery is considered the proper procedure.

The author's references will appear in his reprints.

The Diagnosis of a Foreign Body in a Bronchus*

EDWARD W. SCHOENHEIT, M.D.,
Asheville, N. C.

It is usual to begin a discussion of this kind with the history, however I should like to call attention to the fact that foreign bodies have been discovered in cases in which there was no history of aspirating an object. The patient may remember nothing about it, and the body may have entered the air passages without producing coughing or gagging. McCrae (1) mentions a case of this kind in which the tip of an atomizer was aspirated.

Usually there is a history of gagging, choking, coughing and wheezing, sometimes dyspnea and cyanosis, all of which may disappear afterwards, and oftentimes the physician has been deceived by this cessation of symptoms believing the object to have entered the stomach. Later on when other symptoms appear this occurrence is entirely forgotten.

After a few days' freedom from symptoms, there is usually a return of coughing and wheezing. At this time the asthmatoid wheeze which Chevalier Jackson describes is most apt to be heard. This is a peculiar wheezing sound heard during expiration by placing the ear in front of the patient's mouth. The wheeze is drier than that of asthmatic patients. It is heard best at this time because the bronchus is not obstructed; if the body completely obstructs the bronchus it is not heard.

The symptoms vary according to the composition of the foreign body. Organic bodies are prone to cause a severe inflammation with a sudden rise in temperature and clinical picture of pneumonia, death having occurred in a few days' time after the aspiration of a peanut kernel. Inorganic, especially metallic bodies, may remain for months without producing severe symptoms. There is usually a gradual decrease in weight and strength, persistent cough, sometimes hemoptysis. There may be all the signs of phthisis including fever, but there are never any tubercle bacilli in the sputum. There may be slight leucocytosis. Pain is a rare symptom.

The continuous irritation of the metallic body causes swelling of the surrounding tissues which together with corrosion of the metal increasing its size causes obstruction, fever rises and there is abscess formation, bronchiectasis or gangrene of the lung.

Physical signs depend upon the position of the body and the length of time it has been in the respiratory tract, as well as upon its size, shape and composition. Usually the right bronchus receives the body, due to the somewhat larger lumen and steeper course. Almost always it is a lower lobe bronchus. Physical signs are practically always localized in one lung, but cases have been seen in which there are signs in both lungs. They are, however, more diffuse in the unaffected side. If there is no obstruction there may be little or no physical signs but with partial obstruction the first and most constant is diminished expansion on the affected side which McCrea (1) considers the most valuable sign. There

*Read before the Section on the Practice of Medicine at the Medical Society of the State of North Carolina, Raleigh, April 15, 1924.

is also impairment of the percussion note approaching dullness and flatness with increase in secretion, and diminution of breath sounds over the portion of lung below the obstructed bronchus. Medium moist râles, the asthmatoid wheeze and inspiratory retraction of the apices may also be noted but are often absent. With complete obstruction the signs are those of atelectasis.

The x ray is perhaps the most valuable aid, although ten to fifteen per cent. of all cases do not show anything. Metallic bodies are usually seen, but may be obscured after long residence due to accumulation of secretions and condensation of tissue. Unfortunately certain bodies which are usually organic are nonopaque to the ray and cast no shadows. It is in this class of cases that an early diagnosis and removal are most important. Jackson, Spencer and Manges (2) have found valuable x ray changes in these cases, namely increased transparency on affected side, depression of the diaphragm on affected side, and displacement of heart and mediastinal structures away from the affected side. The increased transparency is due to an acute obstructive emphysema. Later when secretions accumulate and we have a condition known as drowned lung there is increased density on the affected side.

Therefore in our diagnosis although most often made from history, symptoms and signs and x ray, we should nevertheless suspect a foreign body when we have a patient with localized symptoms in one lung, especially a lower lobe, with gradual loss in weight and failure in strength, absence of tubercle bacilli in sputum, elevation of temperature, slight leucocytosis, persistent cough, even though no history is obtained, and we should make every effort to disprove the presence of a foreign body. Some have even advised exploratory bronchoscopy when the x ray has shown nothing.

The following case will illustrate some of the points mentioned and some of the difficulties encountered. The patient was a woman forty-six years old, who complained of severe pain in the right side of the chest, cough and fever. She was admitted to the Winyah Sanatorium November 10, 1923. Past and family histories were negative.

The present illness began after a tonsillectomy with general anesthesia (nitrous oxide and oxygen), July 3, 1923. On the following day she suffered from difficult breathing and wheezing, and shortly afterward began to expectorate phlegm. She continued to lose in strength and to feel run down, but did not know whether or not she lost weight until six weeks had passed when she began to run a temperature of 100 to 101°. Her physician then referred her to an internist who made a thorough examination, including x rays, and diagnosed the condition as chronic, fibroid tuberculosis. She was then referred to us by her family physician.

Our examination was made under difficulty. The patient appeared to be suffering from severe pleurisy, and the right thorax was strapped in order to lessen the pain. Examination of the chest naturally therefore showed less expansion on the right side. The percussion note was slightly impaired in both upper lobes and auscultation revealed harsh breath sounds and a few râles which were not constant after coughing. Below the right axillary region there were râles which resembled those seen in acute pleurisy and the pain was severe at that point on deep inspiration. The sputum had never shown tubercle bacilli although we made numerous examinations. The amount of sputum was not large, contained numerous pus cells and had no disagreeable odor. It did not separate into layers upon standing and there was no elastic tissue. The leucocyte count was 14,000; a blood culture was negative. We did not feel warranted in disturbing the patient for an x ray examination, as we had the report of a competent man.

In considering the diagnosis we felt that we were dealing with something besides tuberculosis, because of the sudden onset after the tonsillectomy. We did not deny the presence of an old healed tuberculous lesion, but the long continued fever which ran from 100 to 102° without remission and the absence of tubercle bacilli and absence of marked apical signs suggested something else. Abscess, gangrene or bronchiectasis did not fit the case. Foreign body was thought of, but repeated questioning did not bring out any history.

After several days, however, the patient remembered having lost the crown of a tooth just before the tonsillectomy but did not remember swallowing it, or gagging or coughing at that time, and had forgotten it. This should have been our clue, though we felt sure that a gold crown would have shown in the x ray plate or that she would have choked on it at the time. The pain also was not indicative of it.

The patient exhibited a temperature of over 100°, and a pulse of 90 to 100 for the following week, but her cough seemed less. The pain still continued. A week later the temperature averaged 99°, and the cough was better. She slept at night without the codein tablets we gave her for the cough. Examination of the chest by this time showed less signs than at any time before and no râles at all could be heard. The adhesive straps were removed.

Improvement continued in this manner until December 11th, when the patient coughed violently upon awakening and brought up a gold crown of a molar tooth with a cupful of thick, ropy sputum.

We then learned that she had had a wisdom tooth extracted while under the anesthetic for the tonsillectomy and that the crown from the adjacent tooth had probably been dislodged at this time. Of course being anesthetized she did not gag nor cough. The crown had been mistaken for a large calcified gland.

We obtained the plate which showed an object in the right fourth interspace which seemed too dense for anything but metal. A fluoroscopic examination showed that this had disappeared. Examination the following day showed dullness at the right base extending to the angle of the scapula. Increased vocal fremitus, tubular breathing, whispered pectoriloquy and many fine râles. Two days after the crown had been expelled the temperature never went above normal. After ten days all the lung signs cleared up and expectoration ceased.

The patient remained in the sanatorium a few weeks to regain her strength and went home feeling well and in good condition.

Cancer of the Colon

E. G. SLESINGER, O.B.E., M.S., F.R.C.S.,
London,
Assistant Surgeon, Guy's Hospital

Cancer of the colon is a disease of great interest to the surgeon, partly by reason of the difficulties it may present, both in diagnosis and treatment, and even more so because of the satisfactory results which follow successful operation in reasonably early cases.

The pathology of this condition has many points of importance in treatment, and none more so than the sites at which it occurs. The pelvic colon is the commonest site by far, next in order of frequency being the cecum, the splenic flexure, the transverse colon and the hepatic flexure. It is at these points in the bowel that the bands developed as a result of chronic intestinal stasis are found, and it is of great interest that the pelvic colon at the situation of Lane's "last kink," so often by far the most markedly obstructive of these evolutionary bands, should also be the commonest site of cancer. It is difficult to escape the conclusion that the obstructions to the passage of the contents of the bowel which develop in Nature's attempts to hold up the heavy, constipated colon represent that irritative factor in the production of cancer which is so clearly recognized in the cancers of the mouth and skin. This relationship between the changes of chronic intestinal stasis and cancer of the colon will be referred to again, but if the correlation between the two conditions is recognized, it offers a suggestion as to prophylaxis which is so important and so little explored a region of the treatment of cancer.

The gross types of cancer occurring in the colon are three, namely the scirrhus, encircling type; the soft, cauliflowerlike, encephaloid type; and the infiltrating colloid type, though the latter occurs far more commonly in the rectum.

Paul long ago pointed out the striking differences in the behavior of these types as regards clinical malignancy, and made the valuable generalization that throughout the body the upgrowing excrescent type of cancer is far less malignant than the downgrowing ulcerating type.

Clogg and others have shown that in the scirrhus growth of the colon malignant cells can be found at considerable distances along the bowel from the site of the stricture, a fact pointing to the necessity of free removal.

Glandular infection in these patients is fortunately late as a rule, and it cannot be too strongly emphasized that enlarged mesenteric glands do not necessarily mean malignant glands, because the septic absorption from the ulcerated bowel surface produces an adenitis far earlier than secondary lymphatic gland infection occurs. Many cases thoroughly amenable to operative measures would be left as inoperable if the mere enlargement of the lymphatic glands of the colon were taken as the measure of operability. Jamieson and Dobson described four groups of glands in connection with the drainage of the colon: 1, the epicolic on the surface of the bowel; 2, the paracolic in the mesocolon close to the bowel; 3, the intermediate along the colic arteries, and 4, the main glands at the origin of the main arteries. In considering the question of operability, enlargement of the first two groups can almost be neglected, and it is the main group that should be most relied on in this respect. These glands are rarely hard and enlarged from sepsis alone, and if such a condition is present it usually means that they are the seat of secondary deposits of growth.

The symptoms produced by cancer of the colon vary according to the stage at which it is seen, depending partly on irritation of the bowel and partly on the degree of obstruction of the lumen which is produced. In themselves the symptoms are, unfortunately, so slight that too often the case presents itself for the first time as one of chronic or acute obstruction. A marked degree of narrowing of the lumen may be produced without symptoms of any kind and sometimes the patient is quite unaware of anything being wrong prior to the onset of acute obstruction. In the early cases the complaints are often slight, there being some discomfort in the abdomen, only occasionally amounting to pain; and the patient feels out of sorts and may begin to lose weight. The action of the bowels is irregular, constipation alternating with diarrhea, and attacks of colicky pain may be felt at times. In some cases the patient may himself have noticed a lump. On ex-

amination a tumor may or may not be palpable. In the pelvic colon the thickened, straight bowel of intestinal stasis is easily mistaken for a tumor especially if diverticulitis is present in addition. Examination of the stools will usually show the presence of blood in small amounts, but this also is often to be found in intestinal stasis quite apart from cancer. X ray examination is of the greatest value, and the presence of a definite filling defect in the colon after an opaque enema, on more than one examination in patients of the cancer age should lead to an exploration of the abdomen. Lane's "last kink" by itself will sometimes produce an x ray obstruction indistinguishable from cancer, and if this is combined with the presence of occult blood in the feces, exploration affords the only means of differential diagnosis. Should such a kink be present, however, its division followed by the careful covering of the raw area with peritoneum, brings such a remarkable relief of symptoms that everything is to be gained by an exploration in such doubtful cases.

When the patient is first seen in a condition of chronic obstruction it is wise, if possible, to attempt to overcome this by conservative means before operation. Several enemata may be necessary before an action results, and in this connection the use of a treacle enema will be found invaluable. Consisting of one part of treacle to three parts of water, and run into the bowel with a tube and funnel, this enema is quite as effective as soap or turpentine, and has the great advantage of acting as a simple nutrient enema should it be retained. Once an action has been secured the bowel can usually be well emptied by paraffin given by the mouth combined with enemata, and operation can be undertaken at leisure. When acute obstruction has supervened, however, immediate operation for its relief is necessary. It cannot be too strongly emphasized that measures directed toward a removal of the growth should never be undertaken in the presence of acute obstruction. The secret of dealing successfully with these extremely sick patients is to do the least possible which will relieve the immediate urgent condition, and to do that in the minimum time. Opinions are divided in these cases between the value of a rapid exploration combined with colostomy in a suitable position on the one hand, and a blind cecostomy with no attempt at exploration on the other. In my opinion both these procedures have their value in suitable cases. In those patients where the distention is pronounced intestinal manipulation is badly borne, and it is here that blind cecostomy, best carried out with local anesthesia, will often tide the patient over a dangerous period when more extensive procedure would have proved fatal. The cecum in some of these patients is enormously distended, and the placing of sutures may prove difficult. Puncture with a trocar and cannula, having first secured the cecum to prevent its slipping, will usually overcome this difficulty and permit the placing of sutures at leisure afterwards.

When distention is not such a marked feature there can be little doubt that a rapid exploration of the abdomen is justified by the valuable information it gives. The situation of the growth can be determined, and an estimate of its operability can be formed, while a colostomy can be so placed at least to interfere with a subsequent operation. Again if the growth is inoperable the question of a possible short circuit can be decided, and if even that is found impracticable the patient is spared the discomfort of a permanent cecostomy with its liquid discharges by placing the colostomy lower down in the length of the bowel. Whichever of these procedures is carried out there should not be too great a hurry to perform the second and radical operation. It is important thoroughly to evacuate the large amount of material which accumulates above these growths, and so to allow the bowel wall to recover its tone before undertaking an operation for removal of the growth. From two to three weeks will be the usual interval required for this purpose.

When the second operation is undertaken, or when a cancer of the colon not complicated with obstruction is operated on, a careful exploration must constitute the first step. The liver should be examined for deposits, and the condition of the main glands at the origin of the colic arteries should be investigated. The local condition is also important, and while extensive adhesion to, and involvement of, the parietes will contraindicate removal, local involvement of other portions of bowel can often be dealt with successfully in this particular type of cancer. By a recognition of the fact that the changes associated with chronic intestinal stasis almost always precede cancer of the colon, its removal will be facilitated. The bands which are formed on the outer side of the bowel and at the flexures are quite separate from the mesentery, and by their division a surprising degree of mobility can usually be obtained in what at first sight appears to be a firmly fixed portion of the colon.

The usual operative procedure adopted in the treatment of cancer of the colon is a local excision of the affected portion of bowel and mesentery, followed by an end to end or lateral anastomosis. This I believe to be an unsatisfactory operation for several reasons. In the first place an adequately extensive excision will necessitate, except perhaps in the pelvic colon, considerable tension to bring the cut ends of the bowel into apposition. Secondly, the feces in these cases are usually inspissated and hard, and the passage of such material over the suture line is liable to produce ulceration and leakage, while the musculature of the proximal colon, being already impaired, is particularly likely to undergo acute dilatation following the operation.

If, however, instead of performing a local excision, the whole colon proximal to the growth is removed with it and an end to end ileocolostomy is used to restore the continuity of the gut, these dangers are largely overcome and in addition several advantages and but few disadvantages accrue. By such an operation in the case of the ascending colon or hepatic flexure very little bowel is removed in excess of what is necessitated by excision of the growth; the removal of the mesentery and its contained glands is facilitated, and the dangers attending the performance of an anastomosis in a portion of intestine without a complete mesentery are avoided. Only fluid feces from the ileum flow over the suture line after operation and the anastomosis can be performed outside the abdomen instead of at the bottom of a deep wound. In the case of growths situated distal to the

transverse colon it is true that the operation appears needlessly severe at first sight, but the actual additional time taken in resecting the proximal colon is small, and if this is done the mesentery and glands can be more fully and more easily removed. The advantages mentioned above apply to the actual anastomosis, and in these cases a large esophageal tube can be easily passed through the junction into the ileum by the rectum and left in place after the operation is completed. This drains away the ileal contents and allows a free escape of gas, thus minimizing the strain on the sutures and rendering the anastomosis almost perfectly safe from leakage. The removal of the colon, which is usually dilated, lessens the intraabdominal tension when the peritoneum is closed and the risks of postoperative ileus are proportionately reduced. The slight technical difficulty of effecting an end to end junction between two portions of bowel of different calibre is readily overcome by spacing the stitches slightly more in the case of the wider end than in that of the narrower one. In a growth of a freely mobile and long pelvic colon, such as is occasionally encountered, the removal of the whole colon is of course unnecessary, as it can be freely excised without subsequent tension, and the anastomosis can be adequately protected by an esophageal tube passed through the junction from the rectum. Finally in those cases which have had a preliminary cecostomy or colostomy performed for obstruction, the removal of the whole proximal colon has the additional advantage that it allows the artificial anus to be removed with the growth and avoids the risks of leakage attending attempts to close such openings.

Metastasis from Symptomless Cancer of Esophagus

GORDON B. NEW, M.D.,
Section of Laryngology, Oral and Plastic Surgery, Mayo Clinic
AND PORTER P. VINSON, M.D.,
Section of Medicine, Mayo Clinic
Rochester, Minn.

The two cases reported here emphasize the fact that cancer of the esophagus, like other primary lesions around the nose and throat, may be almost symptomless for many months. The extensive metastasis, and not the primary lesion, may cause the patient to seek examination.

CASE I.—(A335370).—A woman, aged fifty-two years, came to the clinic September 25, 1920, because of bilateral enlargement of the cervical glands of two months' duration. In February, 1920, seven months before examination, she had had slight dysphagia for a few days, but this was attributed to an ordinary sore throat. In June, 1920, three months before examinations, she again experienced discomfort in the throat without dysphagia, and tonsillectomy was performed. Two months before coming to the clinic a nodule appeared in the upper right cervical region, and later a gland on the left side of the neck. The glands had enlarged rather rapidly since they were first noted. The patient had lost twelve pounds in weight since the tonsillectomy, and had become rather pale.

The upper cervical glands were enlarged on both sides, more markedly on the right. The condition of the glands appeared to be malignant. Examination of the nose and throat and nasopharynx did not reveal a primary lesion, although there was a suggestion of enlargement of the right arytenoid. The hemoglobin was 67 per cent. Because of the history of slight dysphagia seven months before, the esophagus was examined and an epithelioma on the upper posterior wall was found. X ray treatment was advised.

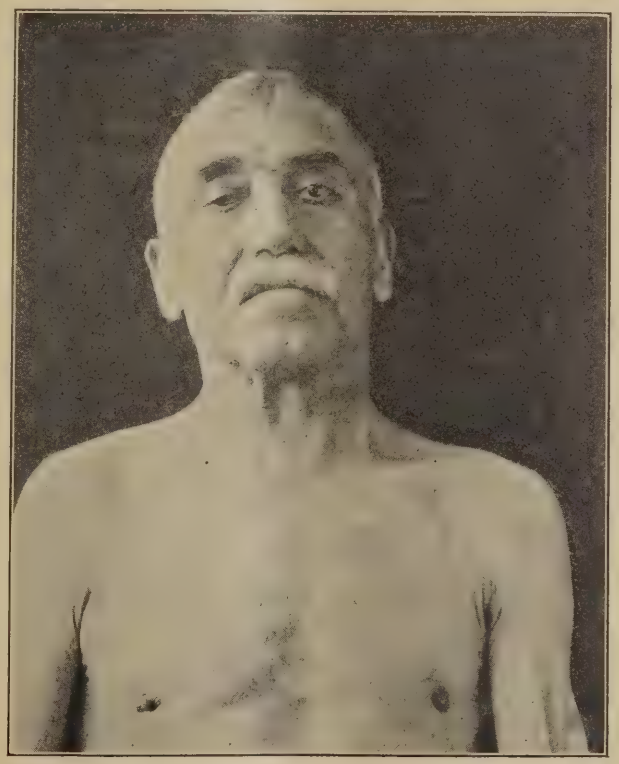

FIG. 1.—A case of carcinoma of the esophagus; note the hard mass in the supraclavicular region, which displaced the trachea and the larynx to the left. A smaller mass just above was also found at examination. (Case II).

The patient consulted Dr. Starr and Dr. Richards of Toronto, and intensive exposures were given over the glands. Marked reduction in the size of the glands occurred following this treatment, and there was a gain of ten pounds in weight. In September, 1921, the patient returned to Dr. Starr for

further treatment. The glands had enlarged considerably and marked dysphagia was noted. Under further x ray exposures, there was slight reduction in the size of the glands with improvement in the general condition, but on December 25, 1921, death occurred suddenly. Necropsy was not obtained.

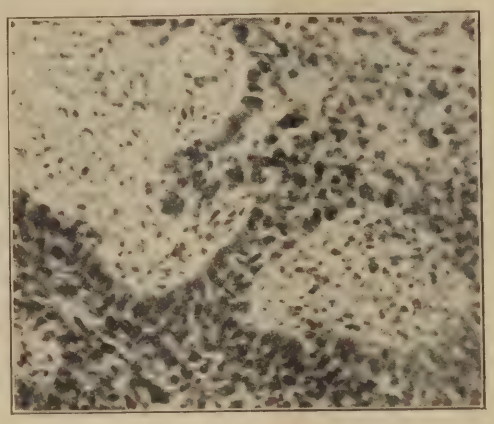

Fig. 2.—Squamous cell epithelioma. (Case II).

Case II.—(A454708).—A man, aged sixty-four years, was examined February 5, 1924. Seven months before, he had begun to have pain in the right supraclavicular region; a nodule appeared at the same time. The nodule gradually increased in size and the pain became more marked. At the end of three months the mass had become so large that x ray and radium treatments were advised, and following these exposures there was a reduction in the size of the tumor, but the pain became worse and was referred down the right arm. Seven weeks before coming to the clinic, hoarseness and dyspnea on exertion had developed, and a week later, obstruction to the swallowing of solid food was noted. The dysphagia had gradually become more marked, until the patient was able to take fluids only.

Examination revealed a hard, fixed mass, five by seven cm., in the supraclavicular region, and a smaller mass just above (Fig. 1). There was also a moderately hard gland in the right axilla, two cm. in diameter. The right vocal cord was fixed in the median line position; there was slight edema of the arytenoids, and the larynx was displaced to the left.

Esophagoscopy under local anesthesia demonstrated a bleeding lesion of the upper esophagus. A section was removed and microscopic examination revealed the presence of a squamous cell epithelioma, grade 3 (Fig. 2).

DISCUSSION

The patient in Case I is of particular interest because of the fact that she did not have dysphagia at the time of examination, and the dysphagia, which she had had seven months before, was very slight and had lasted for only a short time. Her chief complaint was bilateral cervical adenopathy of two months' duration, developing one month after tonsillectomy. The slight enlargement of the right arytenoid, and the previous history of dysphagia made an esophageal examination advisable, as the glands were apparently malignant and as no primary lesion was found in the cavities of the head.

In Case II, the extensive mass in the right supraclavicular region, which displaced the trachea and larynx to the left, and fixed the right cord in the median line was unusual. Dysphagia was present only for five weeks and was attributed to the secondary involvement of the esophagus by the mass in the right supraclavicular region. This case is similar to those in which metastatic masses develop in the neck from a small, symptomless, primary, lesion in the nose or throat. The metastatic mass, however, may be quite extensive, causing all the symptoms for which the patient seeks relief.

The Diagnosis of Spinal Metastases Having a Clinically Latent Primary Focus Within the Chest

THOMAS SCHOLZ, M.D.,
New York

Some time ago (1) we published two cases of spinal carcinoma, one secondary to a primary lesion in the thyroid, the other following a primary focus in the breast, in which owing to the extremely small size of the clinically latent primary tumors the diagnostic side had remained obscure for a long period of time. It was shown at that time that in such clinically obscure spinal lesions one may sometimes arrive comparatively early at a correct diagnosis by fully and properly exhausting all the radiodiagnostic possibilities.

This time we report four more cases of spinal metastases presenting similarly complicated diagnostic conditions. The primary focus in each instance was found to be within the thorax. Here again it failed to give rise to any clinical symptoms for a long period of time. Röntgenologically, however, the primary lesion this time, in contrast to the previous cases, could have been demonstrated early and easily, if anyone had thought of x raying the chest. Yet it was not done, for the reason that, owing to the latency of the primary focus, entire clinical and röntgenological attention, it seems, had been concentrated upon the clinically apparent seat of the disease, namely, a certain part of the spine.

The points which have been touched upon very briefly will be illustrated by the following four cases. It will be shown how important it sometimes may be for the röntgenologist not blindly to x ray only the part of the body asked for by the clinician, but to familiarize himself with the clinical aspect and all the diagnostic possibilities of the individual case and then to lay his radiodiagnostic plans accordingly. Three of the patients came to autopsy at the Montefiore Hospital; in the fourth case, observed at the Lebanon Hospital, no autopsy was obtained, but the

diagnosis was well established by the further course of the disease. As more stress is laid upon the demonstration and explanation of the proper and individual handling of this type of cases than upon a description and reproduction of röntgen anatomical details, it was decided to replace the numerous original x ray plates by plain schematic sketches.

Case I.—L. B., fifty-two years of age, married, a salesman, born in Russia. He had had gonorrhea at twenty-three, previous history otherwise negative. He was admitted into the Montefiore Hospital January 25, 1921, where he died February 3, 1921.

His present illness had a gradual onset eight months prior to admission to our hospital, with pain in right shoulder, lower part of back, and left heel. The pain in the shoulder was dull, that in the back sharp and cutting, and radiating downwards along the posterior surface of the left lower extremity. The pain came on in the form of attacks which varied greatly with regard to frequency and intensity. At the end of three months, during which time the patient had been working at intervals and had been using various liniments, his condition grew worse so that he was no longer able to attend to his business. He then began to make the rounds of the various dispensaries where he was treated for rheumatism, neuralgia, sciatica, and other conditions without any appreciable improvement. Finally being admitted to a hospital, he was given mechanotherapy, whereupon the symptoms became aggravated very rapidly. He left hospital No. 1 in order to enter hospital No. 2, where a tumor of the urinary bladder was diagnosed and operation advised, which the patient refused. He left hospital No. 2 and had an x ray examination done privately. The röntgenologist reported a tumor of the stomach, the spine being negative. The patient then entered hospital No. 3 to be operated upon for the tumor of the stomach. Operation revealed a normal stomach and also failed to furnish any new clue for the solving of the diagnostic problem. On January 25, 1921, eight months after the onset of the symptoms, the patient was transferred to the Montefiore Home in a moribund condition.

A satisfactory and complete physical examination was impossible owing to the patient's condition. There seemed to be dullness over the right apex, numerous various râles over both lungs, marked tenderness over the lumbosacral spine, and a suggestion of loss of active motility of left lower extremity; urine and Wassermann reaction negative, temperature normal.

Röntgen ray examination was made on February 1st, which showed complete obliteration of right upper lobe region; marked enlargement of root glands; advanced irregular destruction within the bodies of the fourth and fifth lumbar vertebræ and within upper portion of the sacrum; small irregular areas of bone absorption scattered throughout the cranial bones. Röntgen ray diagnosis: Multiple metastases in lower portion of spine and in skull, evidently secondary to tumor of the right lung (Fig. 1).

Patient died two days later. Autopsy findings: Carcinoma of right upper lobe with metastatic involvement in fourth and fifth lumbar vertebræ and in the upper part of the sacrum, especially along the sacroiliac joints. Gastrointestinal tract was normal.

Case II.—S. K., fifty-five years old, married, a tailor, who had been in good health until sixteen months prior to admission into the Montefiore Home on April 29, 1919. His family history was negative.

His present illness dated back to December 25, 1917, when the patient fell on the ice and injured his shoulder. Following this a general weakness gradually developed which increased to such a degree that the patient was unable to walk, and had to stay in bed for a period of eight weeks. He then gradually recovered sufficiently to be able to attend to his work. A certain amount of weakness, however, remained and he sometimes had to force himself to finish his daily amount of work. Thirteen months after the accident the patient noticed a small hard nodule in the right axilla, and at the same time his general weakness began to increase. A private physician considered the condition to be due to bad teeth and advised their removal. Soon after the removal of the teeth and quite suddenly, pain started in various parts of the body and increased rapidly to such a degree that the patient soon became bedridden. The tumor in the right axilla increased in size and new growths appeared also in the left. On April 29, 1919, sixteen months after the onset of the symptoms, the patient was admitted to the Montefiore Home.

Physical examination revealed complete paralysis corresponding to the fourth and fifth dorsal segments; large tumors in both axillæ; numerous moist râles in left supraclavicular region. The clinical diagnosis was transverse myelitis, probably due to a metastasis, as suggested by the axillary glands; the primary focus was not definitely known. Laboratory findings were negative.

Röntgen ray findings on May 13, 1919, showed the spine negative, oval shaped, well circumscribed shadow of slight density, about seven cm. at its widest diameter, occupying the region of the left root; small, slightly irregular areas of bone destruction within the occiput. Röntgen ray diagnosis was mediastinal tumor with occipital metastases. Radiographic reexamination of the thoracic spine on May 23d, front view, negative; lateral view showed fine irregular destruction along the anterior aspect of the bodies of the fourth, fifth and sixth thoracic vertebræ, a finding which was interpreted as metastatic involvement (Fig. 2).

The patient died on June 6th. Autopsy findings were as follows: Mediastinal lymphosarcoma, the latter pressing tightly against the anterior surface of the midthoracic vertebræ; slight irregular destruction along the anterior aspect of the bodies of the fourth to seventh thoracic vertebræ; metastasis within the spinal cord on level of second thoracic vertebra; perforation of a sarcomatous retroperitoneal gland through the ligamentum longitudinale anterius, extension of the tumor tissue underneath the ligament upward as far as the lower border of the mediastinal tumor, and beginning invasion by the tumor masses of the bodies of the seventh to fourth thoracic vertebræ (Fig. 3); diffuse metastases in practically every organ.

Case III.—B. F., fifty-six years of age, married, was admitted to the Montefiore Home on July 6, 1915; died July 25, 1915. Her family and previous

Fig. 1.

Fig. 2.

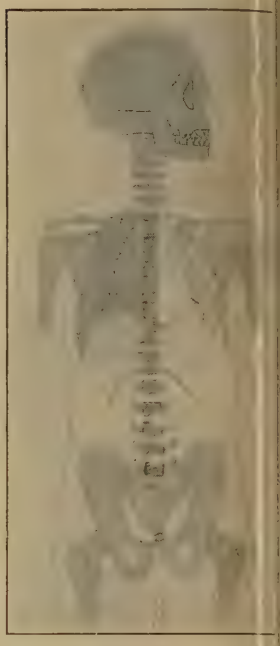

Fig. 6.

Fig. 1.—Schematic demonstration of findings in Case I, showing primary tumor involving the right upper lobe, and metastases in sacrum, lower two lumbar vertebræ, and skull.

Fig. 2.—Schematic demonstration of findings in Case II, showing at (*a*) the primary mediastinal tumor, at (*b*) the level of the compression of the spinal cord by a metastatic focus; within the occipital region several metastases.

Fig. 4.—Graphic illustration of the findings in Case III, showing the primary tumor involving the entire left lung field; metastases within the upper three lumbar vertebræ; some of the ribs and the skull. Within the right lung field there are several small shadows which were found at autopsy to be due to metastases in the pleura.

Fig. 6.—Schematic demonstration of findings in Case IV. Note primary tumor (endothelioma) of right lung and metastases in lumbar vertebræ and upper portion of left femur.

history was negative. Her present illness began eighteen months prior to admission to our hospital when the patient, while walking in the street, suddenly broke down without any apparent cause, was unable to rise and had to be carried home. There was tenderness over the lumbosacral region. A private physician diagnosed the case as fracture of the spine, which diagnosis apparently was confirmed by a röntgen ray examination. As the instituted treatment failed to bring any relief, a second x ray examination was made and an x ray diagnosis of tuberculosis of the spine was furnished. The patient was placed in a plaster cast for five months, without any favorable result, however. On the contrary, the pain in the back gradually became unbearable, and the plaster cast was removed. The patient was unable to stand; at each attempt she "fell down as if paralyzed."

On admission to the Montefiore Home the patient appeared very poorly nourished, was unable to stand up and evidently was suffering great pain. Tenderness was most pronounced over the upper lumbar vertebræ. Every movement of the body was made *en masse,* and caused excruciating pain. A complete neurological examination was therefore not attempted. There seemed to be motor paralysis of both lower extremities. Examination of the chest revealed a suggestion of fluid on the left side. Urine and Wassermann reaction were negative. Clinical diagnosis was metastasis to the spine, probably secondary to a primary focus within the left side of the chest.

Röntgenological examination showed complete obliteration of left lung field, appearance of shadow suggestive of neoplasm; numerous small metastases within the right lung; advanced destruction of upper lumbar vertebræ; several small areas of bone rarefaction within the cranial bones and in some of the ribs. Diagnosis: neoplasm of the left lung with multiple metastases in lumbar spine, ribs, skull and right lung (Fig. 4).

The patient died several days later. Autopsy findings: Primary adenocarcinoma of left lung; numerous small metastases within the pleura on the right side (on the intra vitam plates diagnosed as lung metastases); large amount of fluid in left thoracic cavity; large metastases in the upper lumbar vertebræ; marked flattening and lateral deflection of the spinal cord by a tumor mass on level of second and third lumbar vertebræ (Fig. 5); numerous metastases in ribs; skull not opened.

Case IV.—A. G., fifty-four years old, married, superintendent of a cigar factory, was admitted to the Lebanon Hospital on November 20, 1916, and died on January 23, 1917. Family history and previous history were negative except that the patient had an attack of lumbago five years ago.

The patient's present illness began about one year prior to his admission to our hospital, when he began to notice a slightly increasing general weakness. He found that his former strong will power and initiative were diminishing and that sometimes he even had to force himself to finish his daily routine work. There was no change in appetite, no loss of weight, and no pain.

One morning he was sitting at his desk in the factory, going over the mail, his feet stretched upon the desk. While taking his left leg off the desk he sud-

denly experienced such extreme pain in the lower back that he fainted. He was found by other employees lying on the floor. After a few days of rest in bed he recovered sufficiently as to be able to take up his daily work. A slight dull pain, however, remained in the region of the lower back and this pain sometimes increased in severity especially on hasty movements, rotation and bending of the body. Gradually he became so perceptive of these various pain producing factors, that, in contrast to his former resolute and brusque walking, he adopted a careful and cautious manner of moving about. He suffered great distress from the elevated trains which passed close to the factory, each passing train causing a slight trembling of the building which elicited in him a feeling as if somebody cut with a sharp knife along his lumbar spine. He dreaded the approach of each train and spontaneously tried to eliminate the trembling of the floor by holding to some fixed objects.

The patient was treated by various physicians without any appreciable result. The further course of the disease was characterized by marked remissions. After shorter and longer free intervals the old symptoms reappeared with increased severity. Later the pain in the lower back radiated downwards along the posterior aspect of the left lower extremity. Still later pain in the left hip and a slight cough appeared. Repeated x ray examinations of the lower portions of the spine were negative. The last radiographic observation of the lumbosacral region and the left hip was made three weeks prior to the patient's admission to our hospital and was also reported negative.

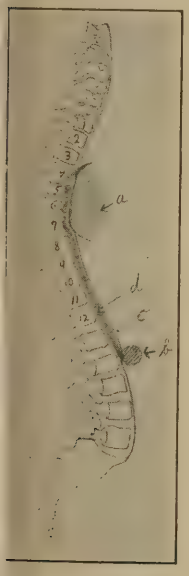

Fig. 3. — Graphic illustration of some of the autopsy findings described in Case II; (*a*) primary mediastinal tumor; (*b*) metastatic retroperitoneal gland breaking through ligamentum longitudinale anterius; (*c*) ligamentum longitudinale anterius; (*d*) metastatic tumor masses growing underneath the ligamentum longitudinale anterius. On the level of the lower border of the seventh thoracic vertebra the tumor masses are seen invading the anterior portions of the seventh, sixth, fifth and fourth vertebral bodies.

Various clinical diagnoses were made, such as lumbago, sciatica, coxitis, and neuralgia. To none of the various corresponding treatments did the patient react favorably as mentioned above; on the contrary, the condition grew steadily worse until the patient finally became bedridden and thus was admitted to the Lebanon Hospital on November 20, 1916.

Clinical examinations by Dr. Henry Roth and the late Dr. William Leszynsky revealed pronounced tenderness over the lumbar spine and in the region of the left hip, restriction of motion of left hip evidently being due to pain, and suggestion of fluid in right thoracic cavity. The patient apparently had lost much weight, but still was fairly well nourished. Neurological examination was practically negative. Clinical tentative diagnosis: possibility of spinal metastasis secondary to an intrathoracic neoplasm.

Röntgenological examination on November 22, 1916, showed a few small destructive areas within the contiguous portions of the second and third, to a lesser degree also of the fourth and fifth, lumbar vertebræ; fine bone destructive foci within the head and neck of the left femur; complete obliteration of the right lung field; slight displacement of the mediastinal organs to left. Röntgen ray diagnosis: metastatic involvement of lumbar vertebræ and of upper part of left femur; primary focus within right side of chest (endothelioma?) (Fig. 6).

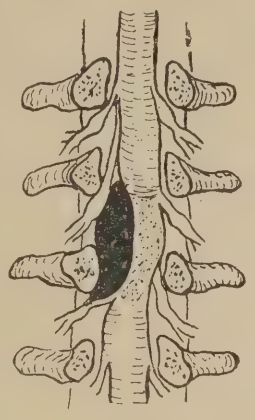

Fig. 5.—Graphic illustration of the compression of the spinal cord by a metastatic tumor mass on level of upper lumbar region in Case III.

Aspiration of thorax two days later gave 160 c. c. of serosanguineous fluid. The patient declined rapidly. Cough and dyspnea gradually dominated the clinical picture. Aspiration had to be repeated every two or three days, each time about one thousand c. c. being removed. The patient died on January 23, 1917, under rapid loss of weight and strength, extreme pain in back and left hip and suffocating cough. Autopsy was not obtained.

The findings in the four cases just outlined again show us the uncertainty and complexity in the diagnosis of spinal metastases. The development of the symptoms is treacherously slow, the course of the disease quite frequently characterized by remissions to such an extent that even the most experienced clinician may sometimes become doubtful as to the correctness of the diagnosis even in cases where the primary focus is known or where it has been previously removed by operation. One may readily see, therefore, how much more difficult the diagnostic conditions may become in cases where the primary focus is not known or where the possibility of malignancy not even is suspected. It is therefore not surprising that these patients pass very soon from the hands of the general practitioner into those of the specialist, usually the neurologist or orthopedist, who, very often with the help of the röntgenologist, tries to solve the diagnostic problem. It is to these specialists that our four patients teach a lesson, the importance of which has been pointed out in a previous article, namely, the importance of general clinical medicine for the specialist. A few more remarks upon this point shall not be construed as a reflection upon the ability of others, but as a desire to aid in the solution of the diagnostic problems in spinal carcinoma.

The related clinicoröntgenological points for consideration may be expressed thus: the clinician referring a patient with a spinal lesion to the röntgenologist should not request the latter to radiograph one certain part of the spine unless he is absolutely certain as regards the diagnosis. Wherever there is any doubt as to some of the diagnostic features, the clinician should explain to the röntgenologist the diagnostic problems to be solved and should leave it to the x ray specialist to work up the case röntgenologically along the lines given. The röntgenologist, on the other hand, should have had sufficient experience in

röntgenology, in general clinical medicine, in gross pathology, and comparative postmortem x ray work, to be able fully to understand the clinical outlines furnished by the clinician, to transform them into röntgenological ideas, to picture in his mind in advance all the gross pathological changes possibly expected, and their radiographic demonstrability, and to lay his röntgenological plans for the examination so that a complete utilization of the röntgen ray method will be assured. If for some reason information by the referring clinician with regard to the clinical features of the case is not available, the röntgenologist ought to be able to obtain the necessary data by taking a brief but exhaustive history. Such cooperation between clinician and röntgenologist will prove beneficial. On one hand, it will avoid making the röntgenologist appear as a plain technician in the eyes of the patient, on the other hand it will protect the clinician against many grave diagnostic omissions and errors. It will make practically impossible occurrences such as those in the cases reported above, where radiographically easily demonstrable, but clinically latent primary foci within the thorax were missed, because nobody thought of x raying the chest.

It has been pointed out lately that specialization is being carried too far nowadays, that there are too many specialists and too few general practitioners. One might be inclined to modify this statement to the effect that there is nowadays a tendency among the specialists, röntgenologist as well as others, to underestimate the importance and value of general clinical medicine. And among the specialists there is none who is as ready to throw overboard general medicine as the röntgenologist. The latter is only too apt to forget that for a solid foundation of a röntgen ray diagnosis one very often has to gather diagnostic building stones from various distant parts of the body, parts that sometimes are situated far away from the clinically apparent location of the lesion. The radiogram of the apparently involved portion of the spine may present, for instance, a bone destructive process, but such a finding, especially in cases where the primary focus is not known, does not necessarily clinch the diagnosis of metastasis. However, if further radiological investigation reveals additional destructive areas in the skull, the diagnosis takes on more definite shape. And if still further investigation produces additional bone destructive foci in the head, or neck or upper portion of the shaft of the femur, or in the ribs, or in other portions of the spine clinically not involved, then the diagnosis of metastases is settled no matter whether the primary focus is known or not, whether malignancy is suspected clinically or not.

Of special interest are the röntgen anatomical findings in the second case. Here were the primary focus, in form of a small mediastinal tumor, and the clinically involved area of the spine situated close together. The involved portion of the spine had been x rayed prior to the patient's admission to our hospital, the primary focus, therefore, also was on the spine plate, but could not be noticed as its contours had been obliterated by the strong penetration and exposure necessary for spinal radiograms.

Attention may also be called to the interesting pathological anatomical process leading to the formation of the metastatic involvement of the midthoracic vertebræ in the same case. A sarcomatous metastasis in one of the retroperitoneal glands on the level of the upper lumbar vertebræ broke through the ligamentum longitudinale anterius of the spine. The sarcomatous tissue then grew underneath the ligament, extending upwards, evidently following the path of least resistance, and undermining the said ligament, but not involving any of the vertebræ. After the tumor tissue had reached the level of the lower border of the mediastinal tumor which tightly encircled the anterior and later surfaces of the midthoracic vertebral bodies, its further growth upward apparently was checked by the tumor mass and deflected into the vertebral bodies which, owing to pressure atrophy caused by the mediastinal neoplasm, probably formed a *locus minoris resistentiæ*. The sarcomatous process in the thoracic vertebræ of this case, as found at the autopsy, therefore cannot be considered a true metastasis.

Finally it might be worth while mentioning that mechanotherapy should be used with great caution in cases of spinal lesion in which the diagnosis is not absolutely and definitely established as nonmalignant. In fact, it would be advisable not to use it at all in such doubtful cases, because there is hardly any doubt that mechanotherapy is very harmful in cases of spinal carcinoma. Comparative röntgenological studies carried on for a long period of time in cases of spinal involvement at the Montefiore Home showed that in several instances of spinal metastases there started a few days after beginning mechanotherapy an unusually rapid growth of the bony metastases.

Similarly unfavorable or even still more harmful effect may follow in spinal metastases, and for that matter in any type of neoplastic metastases, a removal of teeth, as shown by our second case in which extraction of teeth was followed by general sarcomatosis.

There were observed recently by the author two other instances in which one to two years after a successful operation for carcinoma of the breast extraction of several teeth was followed by a sudden outbreak of general carcinomatosis. It might therefore be advisable to pay, in future, attention to such an occurrence and to collect and publish further observations on this point.

CONCLUSIONS

Clinically latent intrathoracic neoplasms may give rise to metastases with severe clinical manifestations.

An early recognition of such latent primary foci may be facilitated by repeated, careful, complete clinical and rontgenological examinations.

The röntgen ray examinations in obscure cases should be carried on individually along lines suggested by the clinical features of the case.

The usual routine radiograms of the clinically involved part of the spine alone very often are of little diagnostic value.

An Unusual Massive Tumor of the Abdomen

JULIUS FRIEDENWALD, M.D.
and WILLIAM A. FISHER, M.D.,
Baltimore

An extensive and unusual massive growth in the abdomen warrants a report of the following interesting case.

Case.—J. W. M., male, aged sixty-three, was admitted to the Hebrew Hospital, June 29, 1922, with the complaint of severe aching in the abdomen while in the standing posture or when ascending stairs. His family history was unimportant. His father died at the age of forty-two, his mother at the age of sixty-two of unknown causes. Two sisters were living and well. There was no family history of cancer, tuberculosis or kidney disease.

The patient's previous health had always been good. He had had the usual diseases of childhood and a severe attack of bilious dysentery at eighteen. He had had night sweats, rheumatism, weakness and malaise and severe pains in his joints eighteen or nineteen years ago. Scarlet fever was present in childhood. He had not had diphtheria, typhoid fever, pneumonia or pleurisy. There was a gonorrheal infection thirty-five years ago, which cleared up thoroughly under treatment. The patient denied having had syphilis. Twenty-eight years ago, he had a fistulo in ano, which was relieved by means of an operation. His habits had been exemplary. Coffee and tobacco had been used to a moderate extent.

The patient had an acute attack of pain in the epigastrium and left hypochondrium last summer, which was relieved by means of hot applications to the abdomen. For the past two months he had had similar pain, less severe, however, but more chronic in character. The pain was at the time of examination dull and aching and increased on standing or on ascending stairs and was in no way influenced by food. The patient had obtained moderate relief by the use of an abdominal support. The bowels moved normally daily, though occasionally there was a tendency to diarrhea. There had been no evidence of jaundice. The appetite was good. There was neither nausea nor discomfort following meals. The patient had slight dyspnea on exertion. There had been neither palpitation nor pleural pain. Edema of the ankles has been observed at the end of the day, especially in warm weather. A loss of ten pounds in weight had been noted during the past three months. His normal weight was 240 pounds; present weight 200 pounds; pulse rate 95; temperature 99°; respiration 22; blood pressure, systolic 130, diastolic 70.

The patient was a well developed, fairly nourished, large framed individual, presenting some signs of recent loss of weight. Numerous moles and nevi were noted over the entire trunk. His head, eyes, ears, mouth, throat and chest organs were negative with the exception of a faint blowing systolic murmur at the apex of the heart.

On inspection the abdomen was found to be markedly distended with the greatest prominence between the umbilicus and ensiform cartilage. There was a definite fullness in both flanks with indications of a movable dullness. On palpation a large mass was revealed about the size of an infant's head. This mass was irregular in outline and extended from the right costal margin in the gallbladder region down and to the left. The mass reached sixteen cm. above the umbilicus, ten cm. to the right, and eight cm. to the left. It extended a few centimetres below the umbilicus. It was hard, firm and smooth, and not tender on pressure. The percussion note over the mass was relatively dull. There was evidence of fluid in the flanks. The mass protruded in the fashion of a ventral hernia when the patient was in the upright pocture.

The liver, spleen and kidneys were not palpable. The axillary, inguinal and epitrochlear glands were enlarged and palpable.

The urine was normal. Wassermann test was negative, blood urea nitrogen 58.24 mgm. per cent., blood urea 124.63, hemoglobin 90, color index 1.1, erythrocytes 4,464,000, leucocytes 5600. Differential count, small lymphocytes 23.5 per cent., large mononuclears 1.0, transitionals 1.0, polymorphonuclears 74.0, basophiles 0.5, platelets normal.

The stool was well formed, dark brown in color and contained no visible or occult blood, and no undigested food particles, mucus or parasites.

The x ray examination of the gastrointestinal tract pointed to a mass encroaching upon the stomach wall together with upper right quadrant adhesions. Based on the loss of flesh, the age of the patient, and the palpable extensive growth, the diagnosis of a malignant growth of the abdomen was made.

On account of the doubt as to the nature of the growth, an exploratory operation was advised; this was undertaken the following day. A right rectus incision was made and the abdomen opened in the usual manner. A large quantity of chylous fluid escaped from the abdominal cavity. The tumor mass filled the entire upper abdomen. It was large, rounded, nodular and vascular, apparently extending up from the left kidney region. It was definitely retroperitoneal and too extensive for removal. A small incision was made anteriorly in the peritoneal covering over the growth and a small section removed for microscopic examination. The peritoneum at the point of incision was drawn together with silk stitches and the abdomen closed in the usual manner. The diagnosis arrived at was inoperable retroperitoneal sarcoma.

The patient stood the operation well, passed a fairly comfortable night, but early the following morning his condition became alarmingly bad; his temperature at 8 a. m. was 102°; pulse 140; respirations 44. He was extremely restless. From this time on he became progressively worse, though nothing abnormal could be detected in his chest. He died the same evening at 7 p. m. Just before death, he vomited a large amount of coffeeground matter.

PATHOLOGICAL REPORT OF SPECIMEN

Material consisted of small bits of tumor from retroperitoneal inoperable tumor. In gross appearance it was very cellular and friable.

Section showed a cellular tumor composed entirely of cells of the small round cell type. Here

Fig. 1.—Anterior lateral view of the growth.

and there was noted a giant cell which in some respects is similar to giant cells of the Dorothy Reed type. Occasionally large areas of fibrosis were observed. No eosinophilia was present, and there was no evidence of tuberculosis. A definite diagnosis in this case rested between lymphosarcoma and Hodgkin's disease. In favor of Hodgkin's was the presence of the giant cells above mentioned as well as the fibrosis. In favor of lymphosarcoma was the uniform small round cells, definitely a little larger than the small lymphocyte, the appearance in the architecture of the tumor, the absence of eosinophilia together with the history of the case, as well as the fact that abdominal Hodgkin's disease is rare. A diagnosis of retroperitoneal lymphosarcoma, small, round cell type was made.

GROSS FINDINGS AT PARTIAL AUTOPSY

The body was that of a well nourished man of sixty-three years. The abdomen was prominent and showed a long right rectus incision partly healed. There were no gross external abnormalities. There was considerable subcutaneous and visceral fat, normal in color and distribution. The pericardial sac was normal in size, position and appearance, and contained a small amount of normal straw colored fluid. The surfaces of the sac and heart were smooth and glistening and of good color. The heart was small, muscle tone and development seemed good. No dilatation or hypertrophy. Measurements 12x12x5.0 cm. Weight 430 gms. The ventricular walls were normal in appearance and thickness, measuring left ventricle 1.4 cm., right .5 cm. The atria were clean and smooth. The coronaries showed scattered patches of sclerosis but were patent throughout their entire lengths. All the valves of the heart appeared to be competent. No thickening of the edges was present. Measurements: mitral 8.7 cm., aortic, 8.3 cm., tricuspid, 12.5 cm. The aorta showed a few sclerotic patches, but the walls were quite elastic.

The pleural sacs contained no fluid. The surfaces were smooth and glistening everywhere except a small area of the right base behind where there were a few fibrinous adhesions to the lung base. The lungs were air containing throughout but showed scattered areas of slight congestion in all lobes. There was no consolidation grossly. The right lung weighed 315 gms. and measured 23x15x4 cm. The left weighed 230 gms. and measured 23x14x6½ cm.

When the abdomen was opened there was visible, protruding from among the loops of intestine an irregular mass made up of nodules about the size of tennis and golf balls, firm and rubbery in consistency. The site of the removal of a small portion of one of the nodules at operation was plainly visible. The mass was found to arise retroperitoneally and posteriorly and was adherent to the spine. It extended from the level of the forking of the aorta up to a level midway between umbilicus and xyphoid. The most prominent nodule was just above the umbilicus. Several of the nodules were attached to the main mass only by their connective tissue and fat. Enmeshed in the mass were loops of gut which could not be extricated without destroying the mass. Just beyond its emergence the intestine was discolored and hemorrhagic in appearance externally. This extended about two feet along the jejunum and beyond this was normal in appearance. The inner surface was normal throughout the entire length. The pancreas was also adherent to the mass, but not included therein. It was not enlarged and had a normal appearance.

The liver was smooth and normal in appearance both on the surface and in section, weight 2,190 gms., measurements 27x19x8½ cm. The gallbladder was distended, no stones noted, all ducts patent.

The spleen measured 14x8x3.5 cm., weighed 225

Fig. 2.—Posterior view of the growth.

gms. The capsule was studded with pinpoint white nodules and a large one measuring on section .75 cm., was cream colored and seemed made up of tissue in layers. It was firm, rubbery, and encapsulated. Splenic substance was normal in appearance.

The stomach was partially filled with a dark brown fluid. The walls internally and externally were normal in appearance and texture. The pylorus showed no abnormalities.

The kidneys were normal in size and appearance. The right measured 11x3x6.1x3.4 cm. and weighed 175 gms. while the left measured 10.5x6.75x3.25 cm. and weighed the same. The cortex in both measured 1.2x2.2 cm. The pelvis of the left kidney was slightly enlarged. Grossly no abnormalities could be made out. Both capsules striped easily. The adrenals together weighed 25 gms., the right being somewhat larger than the left. The ureters were normal in size. The bladder was thinwalled and normal in color. The prostate measured 4.7x3.3x2.3 cm. No nodules were present. The left testicle with appendages weighed 60 gms. and measured 4.7x3.5x2.3 cm. while the right weighed 70 gms. and measured 6.5x4.6x2.6 cm. The sac was distended with fluid.

MICROSCOPIC FINDINGS

The heart muscle was apparently normal, vessels normal. The left upper lung was somewhat fibrous, moderate pneumokoniosis; shadows of red blood cell in the alveoli, in the remainder there was some breaking through of the alveolar walls to form large air spaces (emphysema moderate). There were some pigmented cells in the alveolar walls. Right lung showed same picture. The liver was normal except for some slight fatty degeneration. There was some increase in the splenic tissue, apparently due to edema, no increase in the reticulum, there was a moderate deposition of pigment. A section taken through the large nodule described in the gross examination shows that it was made up of small round cells arranged in layers which were concentrically circular at the outer margins. The cells were of the small round variety similar to those of the original growth. The nodule caused a compression of the surrounding splenic tissue so that the trabeculæ and corpuscles were arranged circularly about the nodule (i. e., new growth). This gave the appearance of whirls about the nodules in the gross specimen.

Sections of intestines were not made. Left kidney showed normal kidney tissue. Right kidney showed a similar picture with the exception of some degenerative change in the tubules which are filled with red blood cells. There was moderate increase in the fibrous stroma of the prostate. The glands were surrounded by a moderate round cell infiltration. They were dilated and filled with secretion. Sections of adrenals and testicles showed normal tissue. The seminiferous tubules contained normal cellular elements including spermatozoa in various stages of development. The intertubular tissue was normal. The cord was normal and filled with opaque staining material. The section of the tumor had, in general, the appearance of splenic tissue. It was made up mainly of small round cells with here and there occasional spindle shaped cells. The growth was most likely a small round celled sarcoma. The microscopic diagnosis was: 1. Retroperitoneal small round celled sarcoma. 2. Metastasis to the spleen. The photographs illustrate the unusual use by any practitioner.

Ligature Treatment of New Growths

ARNOLD H. MAY, M.D.
Buffalo, N. Y.

Several years ago I conceived the idea that if the blood stream was cut off from developing benign or malignant growths, the abnormal tumor mass would atrophy and disappear. With this idea in mind I treated several cases of benign growths, including certain verrucæ, by tightly embedding their bases in a ligature of fine silkworm gut, or other suitable material. In some instances, as verrucæ, the ligature was placed at the very root—or base—of the growth, tied as tightly as possible, and allowed to remain until it fell off. In benign tumor masses it is best to use a subcutaneous ligature—an ordinary curved needle being used to place the ligature at the root of the growth, and the ligature is drawn as tightly as possible, to produce a complete shutting off or occlusion of the blood supply. Subcutaneous malignant growths, prior to metastasis, are treated in the same manner. It is necessary that the ligature include the entire base, or, still better, include the healthy tissue below the base of the growth. Malignant growths to which this method is applicable, show the same successful results as benign masses.

The ligature is kept on indefinitely until the growth shows satisfactory atrophic changes. The earlier the method is applied, the more satisfactory the results.

Following the application of the ligature there is a gradual disappearance of the growth, the masses becoming progressively smaller until they disappear. It is often necessary to apply the ligature several times before a complete result is achieved. It is necessary to include all the pathological tissue in the ligature.

Microscopical examination of the tissue sections of the growths treated by the ligature method shows a progressive pressure atrophy. The cells become smaller and smaller and finally disappear. In many of these cases a fat necrosis or degeneration of the cells occur. There is frequently an accumulation of droplets of fat in the cells, which can be stained by Sudan III or osmic acid. The cells frequently disintegrate giving an oily appearance to the mass. In most cases the cells simply become smaller, the cytoplasm appears perfectly clear, the nuclei are small, and the result is a mass of degenerating cells and cell detritus. Occasionally a process analogous to a dry gangrene develops.

The ligature method is undoubtedly a valuable method of treatment for certain benign and malignant growths. Its simplicity makes it available for extent of the growth.

Cancer of the Hepatic Flexure of the Colon

JOSEPH PEUTOT, M.D.,
Lyons, France

As an introduction to the subject of cancer of the hepatic flexure of the colon I would briefly refer to a specimen successfully excised, followed by ileosigmoid anastomosis and recovery of patient (Fig. 1).

The neoplasm is seated at the superoexternal aspect of the hepatic flexure of the colon. It is the size of a tangerine orange and practically annular in shape. It does not completely involve the internal aspect of the intestinal wall. The lumen of the intestine is reduced to such a degree that the little finger can hardly pass through. The plicae circulares (valvulæ conniventes) have disappeared and the internal surface of the growth is dotted over with small, nonulcerated neoplastic buds.

On section a vestige of the external muscular band can be seen. The cecum is short and dilated; the commencement of the transverse colon somewhat atrophied.

Microscopically the diagnosis was: typical cylindrical epithelioma of the intestinal type.

SURGICAL ANATOMY

In a necessarily limited description of the surgical anatomy of the hepatic flexure of the colon, it is not my intention to refer to all those writers who have studied the topography and connections of this viscus. Only the essential anatomical peculiarities from the surgical viewpoint need be mentioned.

The first question is in what region should the surgeon approach the right flexure of the colon? When one consults the literature of the subject, it at once becomes apparent that there are no fixed landmarks for reaching this segment of the large intestine. This is comprehensible in the case of an organ as variable in position as the transverse colon.

However, it is useful to outline its situation if only for the purpose of deciding between a median or lateral laparotomy as a route of approach. Hence, with I. L. Faure, I will merely say that the right angle of the colon is to be found at the level of the tenth or eleventh rib and we outline the seat by saying that it corresponds to a portion of the abdominocostal wall as follows: two vertical lines map out its lateral limits, one starting at the apex of the axilla is drawn down to the anterosuperior iliac spine, the other parallel to it, but more anterior, passing through the nipple, a parallel line passing through the apex of the eleventh rib gives the lower limit. Hence we have a quadrilateral within which lies the hepatic flexure of the colon, whose internal border is epigastric, the superoexternal hepatic and the lower border prerenal and duodenal.

When an incision of the abdominal parietes is made in the region just outlined, after having raised up the lower edge of the liver, it will be seen that the junction of the ascending colon with the transversed colon is formed in the following way: the ascending colon is nearly vertical; on the contrary, the branch formed by the commencement of the transverse colon is oblique upwards, sometimes horizontal, very rarely oblique downwards. But while the prerenal ascending branch is situated in the same plane throughout its entire course, the transverse is not only directed obliquely to the left, but from behind forwards as well. As J. L. Faure has pointed out, this arrangement is due to the deep situation of the kidney in the adult, on account of increase in depth of the posterior abdominal wall.

The hepatic flexure is consequently deeply seated especially when the liver is large or projects slightly forward and the kidney small in size. It will be found on the right side of the gallbladder to which it is sometimes contiguous, while at other times it may be distant to it for as much as several centimetres. It is in relation to what Jonnesco designates by the name of the internal surface of the right lobe of the liver and it makes an imprint in it in the form of a little hollow situated more or less anteriorly according to the size of the liver, as well as the direction of the transverse colon which frequently recedes from the under surface of the liver. In extreme cases, such as those described by Curschmann, Vianny, and myself, the right angle of the transverse will be found in relation to the convex surface of the liver, but such instances are exceptional.

Behind, the flexure lies in the kidney. Exceptionally it runs along the external edge of the kidney but usually it rests on its lower pole over the antero-external aspect, allowing one to perceive the intero-internal aspect of the kidney where it separates from this organ. In this normal arrangement the pelvis and hilum are to the inner side and above it. However, occasionally the flexure reaches as high as the middle of the kidney. In this case it is rather open and its upper branch along with the transverse colon cuts across the second portion of the duodenum at its upper part. This constitutes the high or duodenal position of the right angle of the colon.

The relationship to the duodenum appears to me to be more important than most writers seem to think. In point of fact, when the surgeon deals with the hepatic flexure, he is often impressed by the contiguity of the small intestine on the one hand, and on the other, that of the terminal portion of the ascending colon when the mesocolon does not exist or is little developed.

In reality, the internal border of the ascending colon at this level lies on the duodenum and when one is not aware of this fact some difficulty may arise in mobilizing the two intestines and especially the application of the clamps which control the hemostasis of this portion of the hepatic flexure.

To this relationship to the second portion of the duodenum when the hepatic flexure is situated high up, an equally important relationship becomes added, namely, that of the hepatic pedicle and bile ducts. Gallbladder, hepatic pedicle, second portion of the duodenum, with the head of the pancreas, such are the visceral relationships which the operator must have in mind when he operates on the hepatic flexure of the colon.

Finally, not only in the pathological cases but normal subjects should be mentioned the very low sitions of the hepatic flexure which may drop down to the right iliac fossa. In reality, the hepatic xure is in the normal state, less strongly fixed an the splenic flexure. Jonnesco, Fromont, Buy d others have described a series of fibrous or peri-neal ligaments at the hepatic flexure, some being nstant, others less so, and some so exceptional at one is led to suspect that these ligaments are erely pathological products. These ligaments as-re the fixity of the hepatic flexure to a certain gree. The more important are the right colic liga-ent, the hepatocolic and cysticocolic ligaments.

The right colic ligament, also called phrenicocolic Prevet, having a triangular shape, is inserted a w centimetres from the costal margin on the lateral all of the abdomen and spreads on to the right lon. Its insertion on the wall is sometimes at a int so far forward that causes the right portion the colon to make a rve with the concavity rwards and to the left. is a semifibrous lamel-ligament, which occa-nally becomes fused th the renocolic and patocolic ligaments, us taking part in fixing e limits of the pericys-fossa.

The hepatocolic liga-ent which, according to ly exists in about one bject out of four, rms a fanshaped pro-ss whose apex is in-ted on the internal as-ct of the vertical lobe the liver at a certain stance from the gall-adder, while its broad se expands over the na cava, the descend-g portion of the duode-m, right angle of colon d anterior surface of kidney. Its shape varies. The cysticocolic ligament is merely a prolongation the lesser omentum which is inserted on the gall-adder and forms a peritoneal bridge between it, the odenum and right portion of the colon at about ght to ten centimetres from the hepatic flexure.

Finally, Buy has described, under the name of ation lamina of the hepatic flexure, a fibrous layer ree to ten centimetres broad, quite pliable, extend-g between the two branches of the hepatic flexure. Such are, briefly described, the ligaments which do t appear to me to play a part sufficient for assuring e fixity of the right angle of the colon. They are t ligaments strictly speaking, but rather peritoneal lds which have no power of fixation and with enard I maintain that there does not exist a sus-nsory ligament of the hepatic flexure of the colon. r that matter, these poorly vascularized folds ve little interest for the surgeon. If they are pres-: their division between two clamps is an easy matter and will not interfere with the liberation of the flexure the seat of a neoplasm.

FIG. 1.—Cancer of the hepatic flexure of the colon.

What is important surgically is that the right angle of the colon can be mobilized. A right angle anatomically fixed does not imply a right angle technically difficult to mobilize; and inversely, a right angle anatomically not fixed does not signify a right angle technically easy to mobilize. The degree of facility in mobilizing the hepatic flexure of the colon depends upon the variable arrangement of the peritoneum in relation to the vascular intestinal pedicle at the level of the ascending colon.

In point of fact, the transverse mesocolon on the right branch of the angle is always sufficiently long so that clamps can be easily placed for hemostasis before liberation of the loop. On the contrary, in the case of the ascending colon the conditions are not the same. The presence of a distinct and rather long mesocolon—although not a rarity in the adult as Jonnesco maintains—is nevertheless not constant; very frequently the serous membrane only covers the intestinal circumference partially. The right parietal layer, after covering the anterior surface of the kidney, connects with the colon and applies the bare posterior aspect of the gut on the prerenal cellular tissue or Toldt's fascia. Then after making the same arrangement on the duodenum it becomes mingled with right layer of the mesentery.

Hence one can understand that in these circumstances a free excision of a cancer of the colon may offer many technical difficulties. A cancer which is not defended by peritoneum on the posterior aspect of the gut may contract adhesions with the retrointestinal cellular tissue and from this fact will be difficult to mobilize and excise. Admitting that these adhesions do not exist, the operator, when the mesocolon is absent, is compelled to work in great depth; it will be difficult for him to bring out the upper part of the ascending colon where its division must be made. The peritoneum having been incised the large intestine must be separated from the duodenum and kidney with which it is directly in contact and then to seize the peritoneal layers and immobilize them. The operation thus becomes almost subperitoneal and presents rather considerable difficulties for assuring hemostasis and to peritonize the raw surface. Then, too, the prerenal cellular tissue will have been bared and the possibility of infecting it will require drainage, preventing union by first intention.

On the contrary, an ascending mesocolon will make things easier. It will be possible to work outside of

the abdomen and to place clamps on the mesocolon for hemostasis with easy suture of the two peritoneal layers. Such are the advantages offered by it.

It is evident that between an absolute absence of mesocolon and the presence of an ascending mesocolon having a breadth of five to six centimetres there exist all intermediary conditions and I have only to envisage the two extremes although it must be admitted that they are somewhat schematic.

Nevertheless, I think it can be said that: 1, surgically, the presence of the socalled fixation ligaments of the hepatic flexure of the colon offers no serious obstacle to mobilization of this portion of the large intestine, and 2, its mobilization will be all the easier the more fully developed the mesocolon attached to it.

Etiology.—The hepatic flexure as I have defined it, represents a rather short segment of the large intestine. By this remark one may be surprised at the number of cases of cancer in this situation. Among the 426 cases of cancer of the colon collected by de Bovis, 26 involved the hepatic flexure. If one takes haphazard other statistics of cancer of the intestine we find the following percentages for carcinoma of the hepatic flexure:

Louart	1 in 76 cases	Korte	5 in 42 cases
Lardennois ..	1 in 36 "	Wittmers ...	1 in 11 "
Barbary	5 in 17 "	Cloog	3 in 25 "
Kessler	1 in 30 "	Rötter	3 in 34 "

In all 20 in 271 cases, in other words, 7.3 per cent.

I do not attribute a statistical value to these figures, but it seems interesting to me to compare those obtained by de Bovis in respect to the socalled seats of election of cancer of the intestine.

Sigmoid flexure	27.3 per cent.
Ileocecal angle	32.2 " "
Hepatic flexure	6.4 " "
Splenic flexure	4.9 " "

These data impose a remark, namely, that cancer of the large intestine has in general a predilection for the angular portions and especially for the hepatic flexure. General etiological factors, age, sex, heredity and general diseases are evidently the same as for the intestine in general. The oldest patient that I have been able to discover was sixty-nine years of age, the youngest twenty-seven.

Among the local etiological factors traumatism has been mentioned, but in the case under consideration it can only have a negligible influence as the hepatic flexure is usually protected by the ribs and liver.

But the proximity to the liver may be a danger for the hepatic flexure, because the former viscus is frequently the seat of cancer and it is not uncommon for a hepatic neoplasm to extend to this flexure. I know of no case of secondary cancer localized to the hepatic flexure.

Pathology.—From an examination of the cases that I have collected it is evident that cancer of the hepatic flexure is usually relatively small. Occasionally the process causes a simple thickening of the intestinal wall, while exceptionally the tumor may attain the size of two adult fists. It is prone to assume an annular shape, but often the ring formed by the neoplasm is incomplete.

Microscopically the growth is made up of cylindrical cells, analogous to the cells of the intestinal mucosa. In the great majority of cases the tumor is an adenocarcinoma or epithelioma, more rarely sarcoma. The epitheliomatous types are most common.

The details of the pathology which are of particular interest to the surgeon are those of the neighboring lesions. There are, in the first place, mechanical changes that arise in the gut in continuity with the growth. When the hepatic flexure is stenosed dilatation and hypertrophy of the ascending colon might naturally be expected; they do exist but never to any marked degree. This is because the stenosis is not sufficiently tight for giving rise to complete occlusion for any length of time.

In nearly all cases the neoplasm will be found surrounded by adhesions. When they involve the anterior or posterior abdominal wall they impede operative work, but in the infrahepatic region this difficulty becomes a real danger when the adhesions involve fragile organs such as the portal vein, renal artery or gallbladder. In these circumstances the cancer will often be found to be inoperable.

Symptoms.—In a very general way, all the symptoms of malignant growth of the large intestine may be met with when the site of the tumor is in the hepatic flexure. From the onset there may be localized pain, disturbances of the stools, violent paroxysms of colic with more or less complete occlusion or alternating constipation and diarrhea. Sometimes the stools will be streaked with blood or a true intestinal hemorrhage may take place. In emaciated subjects a tumor may be palpated through the abdominal wall, which is the terminal point of the peristaltic contractions. Lastly the patient's general health declines, the integuments are tinted light yellow and there is a decided distaste for meat.

But all these symptoms—when the lesion is in the hepatic flexure—undergo such changes that the preoperative diagnosis is extraordinarily difficult, often even impossible. It happens that the most important among them may be completely absent, the cancer remaining latent. Or they may be grouped in such a way that they affect the clinical complex of some other morbid process.

I shall, however, undertake to describe their most usual syndrome and the clinical peculiarities resulting from the topography of the parts involved.

From the functional viewpoint the colon is destined to receive the chyme and to evacuate it intermittently into the rectum. But at the same time it causes it to undergo certain changes that can be understood when the condition of the intestinal contents at the ileocecal valve and in the rectum are compared. Then too, thanks to the intestinal juices secreted by the colon chemical changes arise which transform the chyme into feces.

When the cancer involves the hepatic flexure it is seated in a more or less mobile portion of the large intestine in direct relation to the duodenum and quite close to the small intestine so that its contents are still liquid. Thus, until an advanced stage is reached the growth will not give rise to signs of stenosis or intestinal occlusion. In most instances constipation is present at the onset, but acute occlusion is neither frequent nor stubborn. The paroxysms that it may provoke usually cease from purely medical treatment. The atrocious pain in the early paroxysms is out of all proportion to the lesion and intestinal disturbances.

Gastric symptoms certainly predominate. In one case the stools were perfectly regular, but the stomach was dilated and succussion revealed the splashing sound and there was vomiting.

Compression of the duodenum is also an important factor in these disturbances. As it increases in size the tumor occludes the duodenum quite as much as the colon, either from its bulk or by the bands of adhesions that develop.

Other secondary influences acting on the stomach, but all giving rise to symptoms of occlusion should be mentioned. Such is prolonged retention of the gastric contents resulting from dilatation of the stomach. There is no remission of the vomiting until the organ has become emptied and the food ingested a number of hours previously will be detected in the vomit.

De Bovis, analyzing the functional symptoms of cancer of the large intestine, distinguishes seven types of patients and from the viewpoint of the relative frequency of these types he offers the following percentages:

Constipation	37.2	per cent.
Alternating constipation and diarrhea	20.6	" "
Diarrhea	13.6	" "
Occlusion	12.1	" "
Pain	9.8	" "
Dyspepsia	3.2	" "
Negative or objective	2.9	" "

In going over the cases I have collected, I find that the dyspeptic type is by far the most frequent in cancer of the hepatic flexure. Patients with alternating diarrhea and constipation are second in frequency. Lastly come the patients with diarrhea.

In respect to other functional signs—pain, hemorrhage, tenesmus—comment is in order.

In the first place the paradoxical localizations of pain must be mentioned. Although the pain is usually in relation to the site of the neoplasm, it sometimes is confused with pain of lumbar, renal, renal hepatic or appendicular origin, and in many cases it was located over McBurney's point.

As to intestinal hemorrhage, it should be remarked that the liquid state of the feces has little tendency to favor ulceration of the mucosa. Therefore it is evident that this symptom is relatively infrequent and de Bovis only found it three times in fifty-eight cases of cancer situated high up on the colon.

The tenesmus being all the greater the nearer the cancer is to the anus, it is not astonishing that it is not mentioned in any of the reported cases of cancer of the hepatic flexure.

In respect to the objective symptoms palpation gives very valuable data. One rarely meets with a case in which a tumor can be perceived by inspection of the abdomen. Its small size, its situation under the ribs and edge of the liver, often also traction from the adhesions which tends to fix it to the posterior abdominal wall, prevent it from making itself evident superficially.

Sometimes, however, the case may be one in which the evolution of the growth has been long, the patient is cachetic, the muscles of the abdomen are reduced to a mere shred without contractile power so that the tumor may be seen to project under the wall of the excavated abdomen.

An intestinal fistula opening on the surface of the abdomen needs no comment. The diagnosis is evident.

Crämer has carefully studied the intestinal tension manifested by waves causing vibrations of the abdominal walls. This observer, by this sign alone, has been able to locate an intestinal tumor which suddenly arrested the waves on its proximal side.

By palpation of the painful area one may feel the tumor when it is sufficiently developed and estimate its form, size, consistency and mobility as well. In order to do this it is necessary that the abdominal walls shall be perfectly relaxed and it is for this reason that many surgeons resort to general narcosis. In cachectic subjects in whom one can readily mobilize the growth a diagnosis, even an early one, can be made by palpation alone.

Lastly, deep palpation may reveal a more or less marked dilatation of the ascending colon and cecum. By percussion one will obtain—according to the case, tympanitic sonority, meteorism, or the dullness of a fecal tumor due to stasis of the feces.

Diagnosis.—I have insisted on the infrequency of acute intestinal occlusion in cancer of the hepatic flexure; nevertheless the surgeon may have a case presenting the symptoms of ileus and must search for the cause. The age of the patient, the history, disturbances in the stools, melena and emaciation may lead one to suspect intestinal neoplasm.

But these cases are the exception and as a rule the patients are nearly always dyspeptics. The first symptom that they note is anorexia and often vomiting as well. These symptoms are invariably mistaken for a simple gastric disturbance and a purgative is the remedy applied. Now, one might be surprised at the usual success of this simple treatment which almost always causes the patients' distress to disappear, but the amelioration is temporary only, the gastric symptoms recur in an aggravated form and then the physician begins to look for some disturbance of the gastric secretion or an organic affection of the stomach.

The analysis of the vomit or gastric contents after a test meal, may show a normal secretion of the gastric juices, or there may be some change, for example, a certain degree of hypochlorhydria which does not explain the symptoms.

Vomiting might lead one to suspect dilatation of the stomach and in fact, as I have said, this condition is frequent in cancer of the right colonic angle. But, generally speaking, it is not a large dilatation extending below the umbilicus and giving rise to clapotage. For that matter, when dilatation does exist it is to be regarded as a symptom either of cicatricial stenosis, spasm or tumor.

But before searching for positive signs of cancer one must successively eliminate the hypothesis of some insidious inflammatory lesion, such as tuberculosis of the cecum, or an acute one, such as appendicitis or cholecystitis, and lastly a movable kidney.

A tuberculous cecum forms a mass situated low down and from the onset is fixed in place, while a neoplasm of the large intestine is movable, at least at the beginning of its evolution. Then again, the history of a tuberculous patient generally differs much from one with a neoplasm so that confusion between cancer and tuberculosis is hardly justifiable. Unquestionably a bacteriological examination of the

feces will settle the question, because when tuberculosis of the gut exists, the specific bacillus will always be found.

In twenty-two cases that I have collected the diagnosis of appendicitis was made in five. This can be explained from what we know of the topographical anatomy because, as I pointed out, the right colonic angle may occupy a position low down in the abdomen. On the other hand, the clinical aspect of the affection may be the same in each process, namely, constipation, pain over McBurney's point, rigidity of the abdominal parietes and unbearable pain when rectal examination is made. Finally, a cancer of the intestine may suppurate and like appendicitis provoke a rise of temperature. In these circumstances one must observe the progress of the affection, which is insidious in the case of cancer, generally acute if it is appendicitis.

Upon several occasions a cancer of the right colonic angle has been mistaken for an inflammation of the bile tract or gallbladder. This is because the neoplasm drags on the liver and also because it is not uncommon for jaundice to arise in this affection just as it does in cholecystitis, and some patients with carcinoma of the hepatic flexure have been sent to Carlsbad or other spas on account of a mistaken diagnosis. The symptoms presented by these patients are painful digestive disturbances, irregular stools and most often and usually apyrexia which should eliminate the diagnosis of cholecystitis.

In movable kidney it is usually the right one that is affected. When cancer at its onset manifests itself by sharp pain, simulating a loose kidney, or when the pain occurs in intermittent paroxysms simulating hydronephrosis, a right movable kidney may readily be supposed to exist. Confusion is still more facilitated by the fact that movable kidney is habitually accompanied by gastric disturbances such as occur in cancer of the hepatic flexure. Generally speaking, in order to eliminate the hypothesis of movable kidney, one should take into consideration irreducibility of the tumor and the absence of urinary disturbances. But an ectopic kidney may at the same time be tuberculous or contain a neoplasm, hence giving rise to pyuria or hematuria as the case may be; the gastric disturbances due to the ectopia, added to those of the urinary tract, will then constitute a syndrome that it would be almost impossible to relate to its multiple causes.

However, as time goes on, the symptoms accumulate. The patient emaciates, the skin becomes straw color and meat is distasteful. At times one can either see or provoke peristalsis and feel a resistant mass in the abdomen, so that it is no longer possible to exclude the presence of an abdominal neoplasm.

Besides the digestive tract the adjacent organs susceptible to cancer are the kidney, liver and gallbladder and the pancreas. I have referred to the difficulties of diagnosis of a cancerous kidney. Let us now examine that of the cancer of liver and gallbladder.

Cancer of the liver is usually secondary to cancer of the pylorus. It gives rise to digestive disturbances and frequently to jaundice, especially when the gallbladder is involved. Sometimes the neoplastic mass may even compress the transverse colon or the right colonic angle, and phenomena of occlusion may ensue. The clinical syndrome therefore greatly resembles that of cancer of the hepatic flexure. But in cancer of the liver there is a frequent syndrome that rarely occurs in cancer of the digestive tract, namely, ascites. Then, too, a cancer of an organ subjacent to the liver is usually separated from the latter viscus by a space sonorous on percussion. Lastly, and most frequently, one can differentiate by palpation a cancerous liver with its nodular surface from a tumor in the neighborhood of the liver.

Absence of fatty stools is enough to eliminate the hypothesis of cancer of the pancreas.

By elimination, we can make a sure diagnosis of cancer of the digestive tract—stomach or intestine.

It has been remarked that the majority of these patients with cancer of the hepatic flexure are also dyspeptics, and in point of fact the clinical picture of cancer of the pylorus differs little from that of cancer of the right colonic angle. Hence the difficulty will be to distinguish between the latter process with or without occlusion of the duodenum and a malignant process of the pylorus. Very often one can only reach a probable diagnosis based on a minute history of the early symptoms. Generally speaking, an occlusion of the duodenum will have been preceded by intestinal disorders before the gastric symptoms develop.

Maylard has reported two cases in which a postoperative examination, suggested by his mistaken diagnosis, revealed the presence of very distinct intestinal symptoms before attention was directed to a supposed lesion of the stomach. A very carefully conducted deep palpation upon several occasions, under narcosis if necessary, may give results even in the most difficult cases. But there are too many causes for mistakes, among which may be mentioned a possible ectopia of the right colonic angle and fecal overdistention on the proximal side of the neoplasm —that is to say in the cecum—so that a preoperative diagnosis of cancer of the hepatic flexure should only be made with all due reserve, the results of radiography notwithstanding. In the majority of cases the diagnosis of the exact site of the neoplasm can only be correctly determined by laparotomy.

Evolution and prognosis.—The duration of the process depends much upon the accidents of occlusion or complete obstruction, and I have pointed out that accidents of this kind are relatively rare in cancer of the right colonic flexure. De Bovis is explicit when he says: "The left side of the colon is infinitely more exposed to occlusion or obstruction than is the right," and this observer finds that on the right it only occurs in three per cent. of the cases. Then again, the hard type of cancer with a slow evolution is more commonly met with than encephaloid with a more rapid development. For these reasons cancer of the hepatic flexure of the colon often takes from two to three years, or even more, to undergo its evolution. Surgical treatment when resorted to in time may result in a survival of several years, perhaps even a radical cure.

In all cases where the neoplasm can be mobilized and the patient is in a satisfactory state of health, resection of the growth should be undertaken, a free excision, if necessary, comprising the right half of the transverse colon and all the ascending colon with the cecum, being done. After which an ileosigmoid laterolateral anastomosis is made.

Psychoanalysis of Organic Conditions*

OTTO RANK

Vienna

Psychoanalysis, as is well known, started originally as a therapeutic measure for the socalled nervous diseases. Today, with all justification, it might lay claim to being the most effective radical therapy, for certain forms of neuroses, the socalled psychoneuroses. From the very beginning, it met with the strongest opposition from the neurologists. At first, obviously, because it was not everyone's concern to take up such a new and strange method which was constantly developing and changing. But, in addition, there is a special factor which prevented the neurologists from making use of psychoanalysis.

The factor is this, psychoanalysis has proceeded as a purely psychological theory and therapy of the neuroses, while the nerve specialist deals mostly in actual practice with physical symptoms, whose psychical causations and components cannot easily be seen without further searching. Yet there has been no lack of advanced psychiatrists and neurologists, who, in their endeavors, have attempted to bring the purely psychological point of view into harmony with the physiological and organic points of view. One must acknowledge that in this field, some American investigators have worked in this specific way. As I am not well versed in the relevant American literature on this subject, I can only pick out some names well known to me, and I will ask you not to be offended, if I perhaps neglect to mention others equally important. When I now refer to the work of August Hoch, Putnam, Jelliffe, Pierce Clark and Kempf, as examples, I do so chiefly to show the trend of investigation I mean. But I believe that all of you and perhaps some of these authors themselves would agree with me that these bold attempts promising so much have not yet gone beyond primary endeavors, and that they remain unsatisfactory in many ways. The same applies to the organo-psychological work, somewhat differently orientated, but having the same aim in view, which as you may well know, was introduced many years ago by Ferenczi (Budapest) in his *Studies of Hysteria and Pathoneuroses,* and then continued with so much promise, by Groddeck (Baden-Baden), Deutsch (Vienna) and others.

*Read before the New York Neurological Society May 6, 1924, at the Academy of Medicine.

Today I should like to put before you a new viewpoint, introduced by me, which in the hands of experts seems to me adapted to further the so highly important practical problem of psychoanalysis of organic conditions. I shall first remind you that soon after Freud began to investigate the content of the unconscious, he came up against the instincts, which according to his own words must be considered as a concept on the borderline between psychical and organic. Then soon, the essential factor in the instincts showed itself to be the sexual impulse, at least where repression was involved. The sexual impulse is known as a biological factor, still nearer the organic. Now the most recent analytical knowledge of the unconscious, the understanding of which I have gained from the analyses of neuroses, states that the deepest unconscious in us—not the preconscious, nor the repressed, but that which was always unconscious—that is, the nucleus of the same is the embryonal stage which continues to exist in us all. This statement may appear somewhat bold. But before I can elucidate it further with examples, I want to emphasize specially that it is no theoretical speculation, nor mere heuristic assertion, but the result of long years of analytical experience of the neuroses.

Here I want only briefly to allude to a result of my analytical experiences, from which I can show you how I came to this specific concept of the unconscious. It has been shown from the study of neurotic symptoms in analysis that the original physiological relation of the child with the mother, as it occurs in the intrauterine state, remains the prototype for every later libido gratification in life, even for the special gratification which we call sexual. It has further been shown, that every time the adult ego fails to adjust itself in reality to the substitute gratification for the unattainable womb situation, it then wishes to fly back again to the blessed primal condition where it was protected and completely gratified. But it is not a matter of merely an unconscious tendency to return to the womb, long ago recognized in analysis as womb phantasy. But my new statement implies that the person is actually in the position really to restore the fetal situation, although in varying degrees. And he is able to re-

produce this or that phase of the primal situation in consequence of the embryonal character of the unconscious, which is kept always unchanged. If you ask me how I know this or how I can prove it to you I should have to refer you to the symptomatology of the neuroses, in which I could without exception, trace back attempts to reproduce the prenatal state. Certainly, I cannot show you here in what a complicated, roundabout way, the adult ego reestablishes this primal gratification in neurotic symptoms. This is particularly difficult, because I would have to acquaint you also with the chief hindrance which stands in the way of a complete realization of this biological regressive tendency, and which causes the ego to assume far reaching compromises. This hindrance lies in the conclusive fact, also gained from purely analytical experiences of the neuroses, which I have described as the trauma of birth. Its importance, as the name implies, consists chiefly in the interference with the most pleasurable intrauterine state, and in the repression of this memory of Paradise, which thus becomes the physiological nucleus of the unconscious. As a guard against the biologically inexpedient striving back tendency of the libido, the anxiety experienced in parturition then becomes psychically firmly established.

I hope that you will be patient if these fragments do not convey much to you, for I cannot repeat in a short lecture the results of years of study, or the material which fills a good sized book; besides we are dealing with a special subject. I shall therefore attempt to discuss briefly the material itself and reserve the theoretical valuation for another occasion. I will first start with the well known typical physical symptoms of hysteria. These symptoms not only in their manifest form, but also in their deepest unconscious content, represent on the whole direct physical reproductions of the act of being born, or, to be more precise of single traumatic details of parturition, on which they are neurotically fixed. And so the patient fails to fulfill the original tendency to return to the former pleasurable situation experienced in the intrauterine life. Here first of all we may mention the phenomena of hysterical paralyses, which represent both the immobile stage of the pleasurable primal situation in the womb, and the anxiety associated with the freeing from the same. The typical symptoms of paralysis characterized by contractures, as well as the disturbances of coordination found for instance in chorea minor, clearly resemble the intrauterine position. I can moreover refer to the fact that Meynert long ago traced back the movements of chorea minor to those of the suckling; but I believe, on the ground of analytical experiences that we have to go still further back to the embryonal position and the reproduction of it. Recently, moreover, Kretschmer traced the convulsive attacks of hysteria to preformed storm movements (*Bewegungsstrum*, as he calls it), and the fainting attack to the death feigning reflexes observed in animals. My own viewpoint which considers both means of expression as reproductions of the birth trauma and the intrauterine state, lies between Kretschmer's phylogenetic parallel and Meynert's individualistic explanation. The advantage of my concept, as you will notice, lies in the fact that it allows us to trace back the forms of the hysterical physical symptoms to their final ontogenetic root, which seems to me of special importance, both theoretically and practically.

I must here abandon all idea of showing you the theoretical importance of this concept, for let us say the yet unsolved problems of hysterical conversion and many other problems. I prefer to speak of its practical applications, namely the understanding which it gives of the actual neurotic symptoms, and the consequent possibilities of influencing them therapeutically. Thus, the neurotic disturbances of breathing observed in bronchial asthma, which are a reproduction of the danger of being choked in parturition, belong to the direct physical manifestations of the birth trauma. Also the neurotic headache migraine, which can be used neurotically in so many ways and has different unconscious meanings, goes back to the particularly painful feeling affecting the head during parturition. Finally all attacks of convulsions as one observes them in quite small children, even in the newborn, represent continued attempts to overcome the primal birth trauma. The popular remedy for infantile convulsions of putting the child into warm water, works obviously by gratifying the tendency to return to the mother. The major hysterical attack which manifests itself in the well known attitude of the arc de circle, is not only recognized analytically as a defence against the coitus position, but also as the reverse of the fetal position; in brief it is a defence against the tendency to give birth, as well as to be born, expressed in organic language.

From the analyses of particular cases, one obtains the definite impression, that the later selection of the form of neurosis is determined in a definite way by the manner of the birth trauma of the person and his reaction to it. I therefore believe that this concept of the psychobiological importance of the birth trauma allows us to base biologically the psychical meaning of the physical symptoms. I say this because it leads back to a state which gives us for the first time a real basis for psychophysiological connections and relations in the unconscious. From the reproduction in dreams of birth and intrauterine states, is only a step to the corresponding physical reproductions in hysteria. From these again only a further step to the same purely organic conditions of disease, which with the same form, have also the same unconscious meaning. The transition of these different forms of disease into one another is so indefinite that sometimes a differential diagnosis is scarcely possible. In tracing back uniformly all these phenomena to the primal state where the psychic and physical are still united, we can understand the content and form of the psychoneurotic symptoms as well as of the parallel organic symptoms. This holds good then for the cases recognized as psychical, as well as for those diagnosed organically or neurologically. For from our viewpoint, it is a matter of indifference whether a real cerebral lesion, or a toxic irritant, or a psychogenic trauma, forces the ego to succumb to the everlasting pressure of the fetal unconscious and thus regress to the protection of the primal source of libido gratification. The uniformity of the symptoms from these

different causes, psychic and organic, then becomes quite obvious, and most of the assumed problems disappear. For the person can do nothing else than go back as far along the tracks of the psychophysical development, as the individual fixation of anxiety and the limits of repression will allow.

The practical and therapeutic significance of this insight is as follows: Just as the same symptom can originate from both sides, the psychical and physical, it must also be possible to influence it therapeutically from both sides. Thus it is to be understood, when, for example, quite recently, attacks of bronchial asthma have been favorably influenced through operations on the larynx; as well as recent experiences in the removal of nervous states of anxiety in children, by freeing the nasal passages. The same neurotic phenomena can be cured psychoanalytically —and indeed just as radically—by avoiding the development of anxiety. Perhaps later, one will even prefer this psychical therapy, when one realizes that in children physically operated on, some time later there develop new states of anxiety, which are localized either in a different organ, or are not at all organically determined. So far as I know, this new development of anxiety appears regularly in children who were operated upon under an anesthetic. This is to be explained according to my experience by the fact that the narcotic sleep is conceived by the unconscious as a reproduction of the prenatal state which reacts to it with the outbreak of anxiety experienced in birth.

You see that this biological concept of the unconscious is important, not only for the understanding and therapy of psychoneuroses, but also for certain organic diseases. Indeed from single analytical experiences one gains the definite impression that a great deal of apparently purely organic suffering saves the person from the luxury of a neurotic formation. Certainly it would be more correct to say, that the neurosis is often a more pretentious substitute for the more banal organic suffering, which also has the same cause and the same psychical meaning. Hence it happens also—as one frequently sees—that a neurosis with its counterfeit physical symptoms really is in the position to prevent an actual disease of the same organ, because it is a substitute for it. In the same manner the therapy of the neuroses, simultaneously with the removal of the psychical roots of the suffering, must prevent the patient from producing physical symptoms in their place. On the other hand also, general practitioners and especially surgeons have to be careful not to establish new psychical symptoms, especially attacks of anxiety from the shock of the operation or the anesthetic. But, as I recently heard, this has already been noticed and guarded against by American surgeons, and I only wanted to confirm and to emphasize this point of view from our psychoanalytical experiences. And so I hope that my statements made from the purely psychical side might be borne in mind by the neurologists and some of the specialists in organic conditions who are in the position not only to apply them usefully, but also to make further investigations and to get new material. I shall be quite satisfied if my paper has the effect of making you realize how necessary it is that we should cooperate more closely and exchange views and experiences in order to be able to develop a more perfect theory and therapy of the organic symptoms and diseases.

Selection of Cases Suitable for Psychoanalysis

ADOLPH STERN, M.D.

New York

It is understood that suitable for psychoanalysis, as used in this presentation, signifies amenability to psychoanalytical therapy in the Freudian sense, using the technic of Freud. It is also understood that, because a patient is found ineligible for treatment along these well defined lines, it does not signify that he cannot be treated, and helped by means of some other psychotherapeutic measure, like hypnosis, suggestion; by applying (to the patient or to the environment) knowledge gained from psychoanalysis; attempting to bring about a change in the latter, making it thereby easier for the patient to make an adjustment himself; or by applying any other method, as for instance, simply talking over things. In a strict sense psychoanalysis makes certain demands in various fields upon the patient, which the latter must meet in order that the technic may be applied. To present the nature of the requirements which the patient must possess this paper is written. The aim is to define and delimit the kind of patient who is, at the present stage of development of psychoanalysis, amenable to the application of its technic.

In some instances it is a matter of no great difficulty to decide as to the fitness of a case for this form of therapy. Frequently, great care must be exercised before final decision is rendered; a patient may have to be seen for two or three weeks, before the question is decided. However, some data have been sufficiently well established to serve as guides in selection. It may be stated that within certain limits, the amenability of a patient to psychoanalytical therapy depends upon the diagnosis; namely, the type of neuroses the patient shows.

The question of age is one that comes up frequently. As a rule one might say that a patient past the age of forty-five is not favorable, though most analysts can instance patients past fifty successfully treated by psychoanalysis. However the type of personality, the fixity of the resistances, the nature of the problems which the neurosis presents are better guides than age *per se*.

At the other extreme we have the question of the youth of the patient. Children are amenable to psychoanalytical therapy, though in a modified form;

namely, the analyst assumes actually the rôle of the parent substitute; he makes a conscious effort to become friendly with the patient, stepping out of his psychoanalytical rôle of apparent inactivity. In some instances, even in the case of adolescent patients, the strictly passive rôle of the analyst cannot be maintained, in view of the necessity on the part of the patient to have an actual parent substitute. The patient cannot with safety endure the deprivation of love entailed by the passive attitude of the analyst.

It is a good rule that any pathological physical condition, that may necessitate surgical or medical intervention, be treated before an analysis is begun. Any course of treatment likely to interrupt the analysis for any length of time, should be instituted beforehand if foreseen.

The patient and analyst should speak a language in common, sufficiently fluently for complete and easy understanding. The patient must possess an average amount of intelligence. In so far as possible, the patient should know at the beginning the probable duration of the treatment, and its cost.

IMPORTANCE OF CORRECT DIAGNOSIS

A correct diagnosis is the most important factor in determining the amenability of a patient to the special psychoanalytical therapy. In its present state of development, it cannot be applied in cases of so-called psychopathic constitutional inferiority. A brief outline of the essential characteristics of such a patient will throw some light upon the reasons for such a decision. His exaggerated ego interests and his narcissism make the likelihood of his forming a transference to the analyst a minimum one; along the line of his libidinous endowments, we see a great limitation, in that he shows a sadly deficient development of his object libido, in his capacity to love some one, not himself.

The patient is especially lacking in his capacity to show tender, respectful love, called by Freud, *die zärtliche Liebe*, the sexually inhibited love, the repression of which in the course of things, gives rise in part at least to the inhibiting forces of a conscience of guilt and shame. He shows a deficiency, if not an absence of the concept, ideal, either in the form of an idealized object or of an ego ideal. In his environment, and this is true also in regard to his analyst, he cannot form such transferences, or affectionate attachments, as demand a sacrifice of his narcissism, or even his egotism. As Freud expresses it in connection with his differentiation between narcissism and egoism, the egoist may be able to love, but he will not sacrifice his egoism for his love. The egoistic and narcissistic constitution of the patients under discussion obtrudes itself on every occasion. In these patients, narcissistic wounds cause them to tear away from an environment that is painful, to break out in open defiance and rebellion, in contrast to the feelings of inferiority and guilt produced in both neurotic and normal under similar circumstances. The influence for good of the group upon the patient is minimal. He yields little of his narcissistic or egoistic impulses to group demands. The ego wins out at the expense of the sublimating influence of repression, exercised by the individual, family or group. Altruism loses to self interest and pleasure. These characteristics may be observed in the patient from early childhood, at a time when under ordinary circumstances the effects of repression, in the form of a conscience, of guilt, shame, the development of tender feelings, are in evidence. In short, in the patient there does not develop the inhibiting influences ushered in by repression. He remains egoistic and narcissistic.

The next group of patients presents more interesting material, and makes the decision as to suitability for psychoanalytical therapy a more difficult problem. Some of these patients belong in the group, named by Freud, the actual neuroses, like the anxiety neurosis, neurasthenia; in this larger group belong the narcissistic group of the hypochondriacs. Others among them present features of a psychotic nature, though strictly speaking they are not psychotic; from this group, however, dementia precox patients are recruited. The group of patients here considered, show some of the following briefly outlined emotional traits. As children they are quiet, reserved, perhaps moody; they do not mix readily with those of their own age; they are highly sensitive and withdraw readily into their shells when this sensitiveness is affected; are readily hurt and offended; show no ready tendency to make confidences; they are difficult of access. With the years these traits remain or may become accentuated. The circle of friends or acquaintances is not enlarged; the person remains as a rule closely bound to the family group. Investigation into the love life of such individuals shows little play, especially of the heterosexual love phenomena; they only infrequently, and then not very enthusiastically, form crushes or transferences to those of the opposite sex; attachments to those of the same sex are more common, and often more intense, more emotionally tinged, than attachments to the opposite sex. In the matter of forming interests, of an objective sort, these patients show a meagreness and marked limitation in range. Some of these patients achieve and maintain a strong interest in limited fields of activity.

THE PROBLEM OF MARRIAGE

The neurosis is not infrequently precipitated when the patient is confronted with a heterosexual problem, especially at the time of marriage. These persons are poorly equipped for this situation, in view of the demands that marriage and love make upon the ego, and the narcissism. The question of love does not enter materially into their decision of marriage, which not infrequently is contracted for convenience of one sort or another; or a marriage may be entered upon at the demand or suggestion of parents or others interested; or the person thinks that society will consider him inferior if not married at a certain age. Marriage is then contracted to avoid a stigma, or narcissistic wound. Many patients of this type date their symptoms from the time of marriage. Other causes are also responsible for the precipitation of a neurosis.

The resulting symptoms are in the main of the nature of physical complaints, prominent among them being a myriad of gastrointestinal phenomena; complaints of bodily aches and pains, and the paresthesias; feeling of physical weakness. A comprehensive view of the picture leaves one with the im-

pression that an impoverishment exists in the love life, not because of the absence of love in the environment, though this may be the case, but that the patient is poor in his capacity to love an object; there is a fixed state of the libido, in the patient himself. There is also a great poverty in the content of the phantasy life, which seems to concern the ego interests to a great extent. Even in the phantasy activity, let alone in reality, we find only small evidence of the existence of a love object. We note a great limitation in the emotional life, in the field of object investment.

Frank cases of the psychoses, like paranoia, schizophrenia and the manic depressive group, are as a rule not amenable to psychoanalytical therapy. The early dementia precox, the mild cyclothymias, offer at times difficulty in diagnosis, and for that reason may keep open the question for a time at least as to whether psychoanalytical treatment should be instituted.

MANIC DEPRESSIVE PSYCHOSES

A few words in reference to some of the recent contributions, by Freud and Abraham especially, in reference to the more detailed findings in the case of patients suffering from the manic depressive psychoses and allied states. Both authors have done analyses, in the interval and during the depressive phase of manic depressive patients, and feel encouraged in their results. Analysis is impossible in the manic phase, for the obvious reason that the ego of the patient has gained the ascendency, and is enjoying the complete defeat of the ego ideal strivings. No attempt to give the patient insight, which might entail the necessity of his relinquishing the saturnalia of the ego, could prove of avail. In the interval, and in the depressive phase, psychoanalytical insight on the part of the patient might be of aid in exposing to his knowledge the narcissistic libidinous strivings, the wounding of which has resulted in the psychosis, and the fixation in which has resulted to the regression to that stage of libidinous development, in the process of symptom formation. According to Freud, in a manic depressive psychosis, in the depressive phase which develops upon withdrawal of libido to ego owing to the real or a psychological loss of a love object, the love object by a process of identification is taken into the ego (*einverleibt*), and is treated most unmercifully by the ego ideal, in virtue of the anal sadistic impulses, so prominently developed in these individuals.

Psychonanalytical investigations and therapy, from a clinical point of view especially, concern themselves essentially with tracing out the fate of the libidinous strivings, whether these are concerned with objects or the ego. The transference neuroses, which will be spoken of shortly, have taught us what we know of object libido, concerned in symptom formation. The study of the psychoses has given us insight into the libido strivings which have remained fixed in their development in the ego stage, termed narcissistic, or have regressed to that level in the course of a psychosis. The object of the therapy would then be to trace the libidinous strivings which have been withdrawn from objective investment to ego investment, liberate them from these regressive fixations, and make them available to the ego for the purpose of object investment. Abraham states that improvement of definite nature is noted in that even when recurrences take place during or after treatment the symptoms are less marked and show a change in that there is evidence that no complete withdrawal of libido from object to ego takes place; the object is not destroyed in entirety. The hope for a cure in these cases lies in bringing about libidinous development from a stage of narcissism to object love. There is much of promise in the last contribution of Abraham (*Versuch einer Enwicklungsgeschichte der Libido auf Grund der Psychoanalyse seelischer Störungen*) outside of its immediate applicability to the treatment of the manic depressive states.

TRANSFERENCE NEUROSES

The group of patients most favorably influenced by psychoanalytical therapy is that which falls under the classification of the transference neuroses, so-called by Freud, comprising anxiety hysteria, conversion hysteria, and compulsion neurosis. All three neuroses have this one feature in common, that the libido concerned in the symptom formation is object and not narcissistic libido. It is upon this differentiation that the separation has been made into the narcissistic neuroses, previously considered, and the transference neuroses, now to be taken up. It seems practical to follow the plan previously employed in grouping patients according to some common characteristics, even though the symptoms may vary considerably. In this instance also, the phenomena which the various neuroses have in common, namely the phenomena of object libido activity, and which at the same time serve to classify the large group as one favorable from the viewpoint of psychoanalytical therapy, will be described. It may not be out of place to attempt an exposé of these phenomena by means of a case report, briefly given.

A TYPICAL CASE

The patient that is to serve as an example is a married woman, thirty-two years of age, born in this country. She came for treatment some two years ago, suffering, for ten years before her entrance into analysis, from headaches, nausea, and depression, the three symptoms, usually in the order named, appearing from a wide variety of causes, mostly of an emotional nature. In addition she was, and had been sexually anesthetic during the entire marital life, and on many occasions evinced disgust for the sexual act; often this triad of symptoms mentioned followed the act. The symptoms are given merely to make the presentation a little more complete. In reality they have no concern with the problem in hand, for a patient with other symptoms of a hysteria would serve just as well. What concerns us more is the fate of the libido of the patient, its activity before and since the symptom formation. A history of the childhood of the patient will supply us with the necessary information.

The patient was the youngest in a family of several brothers and sisters. When she was six years of age the family moved from a small midwestern town to New York city. Some of her earliest recollections are the pleasant memories of time spent, before her sixth year, in her father's workshop, watching him at his tasks, and doing minor errands for him. She

felt that she was her father's favorite, and enjoyed the preference. Following the removal of the family to the city, the father ceased to be the object of the tender, romantic affections of the child; in this respect he was replaced by the oldest brother of the patient, who had come to the city some three years before the rest of the family, and had prepared a home to which they could come. He it was who virtually took the position of head of the household, and the little patient worshipped him as her ideal, though he did not return her affections in the same degree that her father had. She was an active child, with a great deal of curiosity along sexual lines. About the age of eight, she went to live with a sister, who had just married, and to whom she became much attached; she also became a favorite of her newly acquired brother in law; about this time, the brother, who had been her ideal, ceased to function as such.

Her sexual curiosity, still quite active at this time, about her ninth to eleventh years, was a source of serious conflict and guilt. Phantasy formation, in which boys served as sexual objects, were very numerous. She was enabled to banish them from her consciousness by an attempt at sublimation in the form of religion. Within easy distance from her home the Salvation Army had established a meeting place; the patient, only about eleven, listened at first entranced at the hymn singing, and the salvation promised to sinners, among whom she numbered herself. She was especially attracted by the Salvation Army lassies, and determined to become one herself. Unknown to her family, she attended as many meetings as she could without exposing herself to punishment at home for her absences, and joined in the singing with as much ardor as the most repentant sinner. She took great pride, and joy in being referred to by members as "Our little sister." She read books which extolled virtue, purity and goodness, and promised redemption. This religious activity was successful in allaying the guilt, and the patient lost her interest in the Salvation Army thereafter.

With the onset of puberty, about the thirteenth year, there was a recrudescence of sexual activity, in the form of phantasy, in which a certain boy of her acquaintance was the object; masturbation was also practised, with phantasies of her love object. At fifteen she suffered from typhoid fever, and became violently enamored in a sentimental, romantic manner, of her attending physician, a handsome young man. Before this incident, about her twelfth year, there again developed a romantic attachment to the brother, of whom she had previously been fond. She became jealous of his attentions to other girls, refusing, however, to believe what some of her girl friends told her, namely that her brother was like other young men as far as women were concerned. Her attitude to this brother was the cause of symptomatic stealing of money, on two occasions. One is especially interesting. She had decided, if the opportunity offered, to get a look at his genitals. While he was asleep one morning, she went into his room, with this motive, and instead of carrying out her plan, she searched his trouser pockets, and took some money. The feelings of guilt consequent upon the thefts were extremely acute.

The sentimental infatuation for the young physician lasted about a year, being unsuspected by him. There was a period then in which no special person occupied her thoughts, and during which time she worked contentedly at home with her mother, with whom she at this time was on more friendly terms than on any previous occasion, owing in part at least to the fact that the sister next in age to the patient, who had been the mother's intimate, had recently married and left home, leaving no rival in the home for the mother's affections. When the patient was just past her sixteenth year she fell in love, again in an ardent, romantic, sentimental fashion, with a young man, a gentile. Association with him was forbidden by the parents, but the patient continued to see him, and to love him, without at any time betraying her love, both because of parental commands, and because the young man did not declare his. At twenty the patient married a man whom she respected, but for whom she did not at the time have any strong passionate love. Before her marriage she confided to her father her serious doubts about being able to go through with the marriage, owing to her feeling so strong a love for the other man. Her father advised her in a kindly way about the inadvisability of marrying, from his point of view, a man of another religious faith, and pointed out in a favorable light, the good qualities of her future husband. The patient acquiesced, and married. She was happy in her marriage, with the exception of the sexual life itself. The phantasy life, which had formed so prominent a part previously, disappeared.

Some misunderstanding with her husband caused her to withdraw her affections from him, and at the same time there was a recurrence of her abandoned phantasy activities, chiefly in connection with her last love object. This took place about three years after her marriage. The return of the phantasies was accompanied by depressing feelings of guilt, and self recrimination. About two years later, her one time favorite sister, the oldest, died. The symptoms of headache, nausea and depression then made their appearance. They often seemed to come out of a clear sky, lasted from a few days to a week or two, and then disappeared. The nausea and headache would disappear sooner than the depression.

This in brief is the history of a patient suffering from hysteria, a transference neurosis. A glance at the account of her history before the onset of her neurosis discloses a typical libido activity in a patient who lends herself favorably to psychoanalytical therapy. The patient seeks to effect a disposal of her libido to objects, and when these for one reason or another are unsatisfactory, the libido is withdrawn from the love object, not to the self or ego, but to the love object recreated in the phantasies. There exists in such patients a mobility, a pliability of the libido; a facility in displacing it from object to object, or to interests (religious as described). God and the Salvation Army sisters became the objects invested with love, when that could not with acceptable gratification be expended upon love objects, phantasied or real. Such patients are amenable to psychoanalytical therapy by virtue of a capacity to make transferences. They show a development of their libido beyond the stage of narcissism, in which the patients previously described show a fixation.

40 West Eighty-fourth Street.

Technical Problems in Psychoanalysis*

C. P. OBERNDORF, M.D.
New York

Quite aside from the light which psychonanalysis has cast upon many intricate problems in ethnology and art, pedagogy and sociology, and ignoring the hopes which it theoretically offers as prophylaxis in mental and social hygiene, the prime interest of the medical clinician centres in the application of psychoanalysis as a therapeutic measure and it seems likely that interest in the method will thrive or dwindle in proportion to the successful results which those employing it are able to demonstrate in treating functional nervous disorders, accompanied by or without physical manifestations. Even brief experience in dealing with clinical problems as they are presented to the psychoanalyst reveals many perplexing situations and shows the need for delicate judgment in the matter of selection of cases and of technic in their treatment.

In commenting upon the technical application of psychoanalysis, a patient who had had experience with two physicians remarked, "Two individuals, taught by the same master, may play the same tune on the same instrument according to the same technic and yet the sound be very different." I might add that were this same tune produced identically by the two players it might convey a widely divergent impression to each of two auditors. In reality during psychoanalysis about five sixths of the tunes are produced by the patient, who cannot help but listen to the sounds he emits and who naturally enough expects some comment upon them from the physician.

The secret of successful psychoanalytical therapeusis lies in calling to the attention of the patient the type of sound he is making and why it appears to him to be a discord or a symphony, a dirge or a jazz, but if the analyst does this too abruptly or too insistently in a key which the patient is not prepared to tolerate, the latter may leave to the former the barren option of terminating the duet as a solo. He will not linger to be enlightened as to what his unconscious reasons are for disliking the particular brand of melody he himself produces or the analyst allows to fall upon his ear.

Technical formulations do exist which may be considered as standards for psychoanalysis and which it is desirable to maintain as strictly as feasible, but these neither can nor should be considered absolute. Psychoanalysis aims for a most impersonal contact between physician and patient, but the personality of the physician cannot be entirely eliminated—revealing itself in the tone of his voice, phraseology and even in his very impartiality and impersonality. This accounts for the fact that occasionally a patient will cooperate better—technically speaking, transfer better—with one analyst than with another and thus allow sufficient time for the physician to bring to consciousness the motives for the particular attractions or antipathies which the patient exhibits.

*Read before the New York Neurological Society, May 6, 1924.

SELECTION OF CASES

Assuming that the patient has agreed to select the analyst, the latter must discriminate in the type of cases suitable for treatment. In the first place, the differentiation of psychogenetic from organic conditions often is the most vexing proposition encountered in medicine. Many a skilled diagnostician will confess if he be truthful, that a suspected gastric ulcer has turned out after laparotomy to have been a gastric neurosis and that autopsy has sometimes revealed that persistent vomiting called hysterical had been caused by constricting and occluding intestinal adhesions. Analogous situations might be cited in connection with every specialty in medicine.

Therefore, we should be as certain as possible that the malady is preponderatingly functional before attempting psychoanalytical treatment. If physical basis for the complaint is excluded, a corroboration of the negative findings by other physicians is an aid. Even in conditions where the physical complaints are apparently trivial, such as headache, insomnia, or indigestion, selection requires discernment. Thus a man of twenty-six with a mild case of glycosuria—one per cent. on a full carbohydrate diet—showed so many nervous symptoms that the medical visiting physicians of the hospital requested an investigation into his personality. He suffered from a typical masturbation conflict. After a thorough consideration of all factors, it seemed advisable temporarily to ignore the organic side and treat him psychologically rather than dietetically and medicinally.

Where the nervous disorder is confined to mentation, without any conversion of the psychic conflict into somatic symptoms, it is essential that the patient himself recognize the condition as abnormal (technically known as insight). Psychoneuroses as a rule are associated with a considerable amount of mental depression, and the differentiation between such incidental dejection and the retardative, self-accusatory depression seen in the manic depressive psychoses may not be simple, particularly because the patient has insight in both these maladies. During the phase of active depression in a manic depressive psychosis, psychoanalysis is not only ineffective but is likely, through forcing the contemplation of painful psychic factors, to intensify the pathological mood and delay recovery. Psychoanalysis undertaken during the interval between manic depressive attacks as a prophylaxis against recurrence (L. Pierce Clark) appears theoretically reasonably valid in those types of recurrent depressions which seem to be a regressive protective defense reaction against external demands or internal urges which the patient because of unconscious motives feels inadequate to face. Convincing proof of its permanent therapeutic efficacy must, because of the normally intermittent course of this form of psychosis, remain in doubt for many years to come.

The approximation of some of the symptoms ac-

companying the neuroses to those of the dementia precox group is occasionally so gradual that the experienced psychiatrist may long question the type of disorder confronting him. The dementia precox (schizophrenic) reactions are serious mental involvements, embraced in the term narcissistic neuroses of Freud, and are not very amenable to analysis. In such cases a persuasive reeducation of the patient, dictated by a psychoanalytical knowledge of trends commonly likely to motivate the symptoms presented, takes preference over true analysis. Where a well organized paranoid trend exists, the prospect for a cure by psychoanalysis is almost as hopeless as it has been by previously available methods.

CONCERNING SUGGESTION

The adoption of the conversational waking procedure vitiates the validity of the accusation that the associations discovered during psychoanalysis are suggested to the patient, who is usually of the type particularly susceptible to suggestion. The fallacy of this criticism becomes apparent after a slight acquaintance with neurotic patients. They resent with a vigor which may amount to defensive dishonesty, any imputation which they consider disparaging to their conscious ideals and many disclosures made during analysis are such as the patient has come to consider, through education or otherwise, as discreditable. This makes it impossible for the analyst to suggest associations in the ordinary sense.

It has been implied that the procedure as a whole is nothing more than an elaborate system of suggestion; that the practice of telling a patient that his habit disorder is due to faulty mental adjustment or to some repression which when brought to consciousness will cure him, constitutes in itself a powerful systematized suggestion. Such a criticism cannot be refuted in toto. Certainly clinical experience has shown the impossibility of forcing specific suggestions upon a patient—damaging or otherwise—for these elicit no response from the patient's unconscious and the seed of suggestion falls on barren soil. If there be any suggestion whatsoever, it is indirect, impersonal, unspecified and the fact of its acceptance by the patient is of positive, corroborative value to the physician who knows its significance, because as a result of his investigations, he has gained an insight into the patient's secret yearnings, forbearances, struggles and conflicts from earliest infancy. In contrast to older forms of suggestive therapy by hypnosis or persuasion, psychoanalysis intentionally avoids specific, determinate suggestion and whatever the patient chooses from the mass of possibilities presented to him in the course of treatment, he does only because it fulfills some unconscious need.

If psychoanalysis had accomplished nothing more than this individualization in the consideration of factors producing nervous symptoms, it would represent a distinct advance toward the better understanding of functional disorders, consistent with the personality and temperament of the patient.

TECHNICAL CONSIDERATIONS

As a curative measure psychoanalysis is most promising in cases of psychoneuroses in intelligent, though not necessarily exceptionally well educated, persons of either sex between the ages of fifteen and forty. Although one opponent of psychoanalysis would advocate a law to prevent its application upon adolescents (1), the most striking cures have been effected in just this group. As a matter of fact, persons beyond forty years of age, because of their mental rigidity, are, generally speaking, not the most favorable subjects. As regards age this dictum is by no means absolute, and depends more particularly on the mental plasticity of the patient, for some individuals at fifty show slight evidence of evolution from primitive emotional reactions.

For obvious reasons the native language of the patient should be that of the examiner, and the analysis should be performed in the environment and country where the immediate conflict exists. Not less than four hours a week for four months or more must be devoted to the procedure. Often a more or less diagnostic, tentative series of five analytical hours may be advisable to learn how the patient reacts, but before prolonged treatment is undertaken an uncolored explanation of its nature and the results to be expected proves most satisfactory to physician and patient alike in the end. While a positive cure should never be offered, the acceptance of a patient for treatment is a tacit implication by the analyst that an improvement is to be expected. It is perfectly justifiable to attempt to overcome the initial rationalized opposition, though urgent persuasion of the patient to undergo treatment is a technical error. Early resistance to the revelation of unsavory sexual experiences gradually vanishes after the analysis has actively progressed, and the patient appreciates that these occurrences entail no personal significance for the physician but are regarded in the light of dry facts, arousing neither sympathy nor censure.

Patient and physician should preferably be total strangers before the commencement of analysis, in order that the impersonal attitude in the treatment may not be influenced by preexisting tendencies and prejudices which are found in every acquaintanceship. Intimate previous associations, while not an absolute bar to analysis, contribute a heavy handicap for both parties. The same holds good for social association with the analyst, so often tentatively essayed by the patient during the course of his treatment and for discussions of the case with members of the patient's family. Interviews with the latter only lead to distortion or misrepresentation of the physician's aims in the sittingroom controversies which invariably ensue at home after the relative's visit, and this complication is precluded if the affair remains restricted to the patient and the physician. At the initial conference the exacting requirements of treatment should be explained to the patient who should assume the task of making necessary arrangements with the persons upon whom he is dependent.

Family opposition forms a stubborn and annoying form of antagonism and is particularly baffling as it operates clandestinely and inaccessibly, emanating from sources beyond the control of the physician. Seeing scant evidence of improvement in the patient, as may be the case even after considerable time has

been spent in analysis, they advance well defended objections to continuation on grounds of practicability, feasibility or expense.

People usually select the most agreeable way offered for the solution of a difficulty and psychoanalysis cannot in any sense be represented as a remedy of unalloyed pleasure. Compared with a trip to California or a cure at a spa with a companion or nurse, it offers little to attract a pampered neurotic and a mere statement of the laboriousness of analytical procedures often prevents acquiescence to treatment.

Moreover, predictions concerning the length of time required before the distressing symptoms may begin to disappear, to say nothing of a complete cure, can be only vaguely ventured, for it is quite impossible until an analysis has penetrated to some depth to gauge the extent and intricacies of the patient's thought ramifications or the tenacity and the strength of his resistances, especially the defense of his narcissism. After analysis is well on its way, it is not uncommon to hear a spontaneous avowal of the realization that the desire to be cured lacked complete sincerity because of the secondary gain in the way of self pity or attention which the illness yielded the sufferer.

CATHARSIS AND PEDAGOGY

A patient once remarked after a few hours of conversation, "There is something mentally invigorating—I might say spiritually cleansing—in getting this off my chest." Nevertheless confessional history or mental catharsis, though incidental to psychoanalysis, is not analysis, and will, except in the mildest cases, leave the patient quite as perplexed in regard to the unconscious factors responsible for his symptoms as he was before. Indeed, one patient reported that she had been sharply scolded by a physician for withholding something, when the symptoms failed to disappear through confessional treatment. Assuredly she could not be expected to reveal what she had forgotten—perhaps did not even know.

The study of the patient's personality may have led the analyst to definite conclusions as to the patient's needs when viewed objectively, but he should make no insistent attempt to impose these opinions upon the patient. It might be his conclusion that a change of occupation or environment or a marriage would prove beneficial but instead of ordering these changes, the analyst would gradually undermine the inhibitions and resistances which tended to keep the patient in the existent undesirable situation, until he would find himself drifting voluntarily toward the appropriate goal. On the other hand, if the analyst is forced to undertake counseling, as he sometimes must at the outset of a treatment begun at the time of a situation fraught with delicacy and possibly peril, the advice should be guarded—rather an enumeration of alternatives than direct counsel. In this respect psychoanalysis differs radically from most other medical measures. One of my favorite responses to the ever recurring demand for advice or a decision is, "It is not what I think but what you think that counts."

To what extent the analyst is warranted in assuming interference and direction is still a mooted point. Ferenczi (2) in 1919 wrote of the desirability of inducing the patient to relinquish the security which his fear affords him and to attempt to face those very situations which he fears most or feared most in childhood. The object of this active therapy is not a cure through persuasion or reassurance of the patient of his ability successfully to meet the apprehensive situation, but aims to uncover fresh, previously unrevealed analytical material. Recently a tendency has developed to emphasize this idea of active therapy with a view to hastening the therapeutic results.

Psychoneurosis is paramountly a mental disorder found among the intelligent and educated, but it is occasionally encountered in those who are unable to grasp the methods and aims of analysis. In such persons treatment must be attempted by other methods, such as suggestion, hypnosis, persuasion or reeducation.

There is a definite distinction between the approach to psychiatric problems in an advisory or pedagogical capacity based upon a knowledge of psychoanalytical interpretations of symptoms shown and the complete analysis with a revelation to the patient of his unconscious motives so that he may, subsequently, independently determine upon his course of action. Socalled psychosynthesis should occur spontaneously as the result of analysis. Such psychoanalytical pedagogy is especially indicated in the minor neurotic disorders of childhood and adolescence and the psychotic episodes of the constitutionally inferior.

The vexing problem as to how much reeducation and advice is to be interspersed in an analysis, how thorough and deep an analysis should be in each particular case, and even judging when an analysis is finished, can only be determined after long experience and is bound to vary with the needs of the patient, to say nothing of the inclinations of the analyst. There is no question that in certain cases the analysis which is not so profound may produce more satisfactory curative results. Many a time when the unconscious is revealed to the patient with the greatest of caution, his reaction may be such as to cause him to rebel against the entire procedure and discontinue in a badly confused state or the situation disclosed may be virtually irreconcilable with actual exigencies.

Experience with these irksome family situations warrants the opinion that in some cases an analysis spread over a longer period of time—a year or more—may possess an advantage over a more intensively applied process in that it allows the patient greater leisure to become consciously acquainted with the type of personality which emerges when his inhibitions are removed and also permits people about him—especially members of the family—additional time to adjust themselves to the new individual appearing in their midst. One man put it, "Psychoanalysis has shown me a new world but whether I can move about in it without smashing up is another question."

Psychonanalysis cures through the revelation of unconscious motives and through the overcoming of inhibitions and resistances—from my experience the latter, especially those resistances which tend to in-

trench the person in narcissism, appear to be far the more important. Such resistances must be called to the attention of the patient again and again—each root which nourishes the trunk of narcissism traced, minutely examined and eradicated. Often he understands the reasons for the pathological condition so well but can overcome them so very, very slowly! To quote again, "Psychoanalysis has brought me by devious pathways right up to the gates and now I feel I cannot enter." And again the resistances must be reconsidered.

Happy therapeutic results in sex abnormalities, impotency, masturbation, etc., are at times attained where the unconscious is barely touched. When neuroses persist well on into adult years, the infantile roots of unconscious longings must be revealed to a greater degree, but I think it unquestionable that many pathological impressions, especially in regard to sex, can be moulded through psychoanalytical insight and technic, with little unconscious material being brought to light, at the time of the momentous physiological and psychological changes coincident with puberty. Assistance at such a time is of enormous importance in determining whether the individual shall revert back to infantile psychosexuality or progress to the point where he can fall in love. While analyses show that many of the causes (misinformation, shocks) to which neurotics attribute their failure in sex adaptation are socalled cover memories or accentuations of isolated details which harmonize with infantile impressions, it is more than likely that proper information and careful instruction in sex matters at opportune moments, according to analytical precepts, would have gone far to produce adequate adjustments.

SPECIALIZATION IN PSYCHOANALYSIS

The question has been raised as to the validity or necessity for specialization in psychoanalysis on the part of the psychopathologist. The reply is that the attitude of impartiality and impersonality in psychoanalysis differs so essentially from the directing and advising viewpoint assumed by and expected of the practitioner in other branches of medicine, that it is almost impossible for the physician in the habit of using the latter method to alternate his attitude from hour to hour with sufficient certainty not to interfere with his effectiveness either as an analyst or a director.

Psychoanalysis will in the end survive or fall as a method, quite regardless of the truth of its theory, upon the cures which it produces. Some day a short cut or an abbreviation of the technic may be discovered—certainly it is to be desired. Anent the failure of the present method at the hands of competent psychiatrists, one may assert, without the slightest impugnment of their psychiatric skill, that this is in a large measure attributable to lack of familiarity with psychoanalytical technic, which must be constantly practised for the attainment of efficiency. This means a thorough knowledge of Freud's theories, an analysis by another analyst and an acquaintance with the manifest mechanisms shown in functional psychoses; through the detailed study of the thought content of dilapidated dementia precox and rampant manic cases in which Freudian mechanisms are so evident, that no analysis is required. A second avenue of approach to psychoanalytical proficiency is through the initial study of those mild neuroses which differ only slightly from normal reactions and through the field of normal psychology, which Freud's ideas are rapidly invading.

A word in regard to a tendency to make something akin to a cult of psychoanalysis. A patient having considerable acquaintance with psychoanalytical practice and literature described it as a system which is "the last word in conventionality and orthodoxy, which pretends to be free but which worships ritual." Behind this exaggeration lies just enough actuality to warrant a brief refutation. Psychoanalysis might easily be transformed into a rigid code or creed, standardized according to the formulations of Freud with an *ipse dixit* as a criterion and a cry of heresy at each deviation. Such an attitude which is really quite foreign to the modest spirit or moderate practice of Freud, must in the end stifle scientific investigation of psychic problems and react unfavorably to therapeutic success.

Most well qualified psychoanalysts have had considerable experience with the methods of the older schools of psychiatry (Kraepelinian and kindred systems) and with purely empirical attempts to influence neurotic disorders. They have found that the therapeutic outlook with the measures available under these systems is distressingly discouraging, unless the diseases (such as alcoholic, infective exhaustive and manic depressive psychoses) are in their very nature self limited.

And yet, it would be misleading to convey the impression that all cases which satisfy the ideal requirements for analysis, namely insight, desire to be cured, and satisfactory financial and environmental conditions, always are cured by analysis. So far as I know, failure in such cases has been encountered by the most competent physician analysts. At present earnest investigations are being made by analysts the world over to discover where the fault lies. Many physicians are inclined to attribute it, first and foremost to their own shortcomings, especially mistakes in the handling of transference, but its failure may also be ascribed to a lack of adaptability of certain patients to the method, particularly that type of persons who has no likes or dislikes, or who is content to give up after short-lived efforts.

Nevertheless from a long experience in the continuous practice of psychoanalysis in selected cases, I can assert that while the results were not unqualifiedly successful in each instance, they had been infinitely more satisfactory than one finds recorded by previous methods in the treatment of psychological abnormalities. Only those who have had a minute inspection of the mental martyrdom which accompanies these psychosexual difficulties can fully understand what the rending asunder of those invisible fetters which enslave freedom of thought and action, means to the sufferer.

A Note on False Confession

RALPH REED, M.D.,
Cincinnati

The psychology of confession has been inadequately studied. The motivation of normal confession is complex. Between lovers mutual confession is common. Here it might be considered a kind of psychic exhibitionism, a mutual unveiling. It also serves to awaken common sympathy and tenderness, but more important, it favors the process of identification, an important element in love, since it enables each to identify himself not only with the other's present but also with his past. Then also we occasionally witness the demand on the part of one lover that the other confess. It is usually the man who makes this demand. It then constitutes an unwarranted form of sexual aggressions. The impulse to confess when confession is undesired and inappropriate might also constitute an aggressive impulse as in the case to be outlined. Confession in this case was thus an aggression and a lure similar in this respect to the obscene joke.

The effect of confession *per se* in its relation to analysis should be studied. No doubt in itself it has something to do with the development of a transference. It may also be one of the motives of negative transference. To the extent that the person does not wish to confess there must be an element of hate engendered against the one confessed to, because to confess means to surrender some precious part of oneself into the hands of another, to give up to some degree one's sovereignty over the kingdom of himself.

During one of my earliest analyses I had occasion, suspecting the development of a mastoiditis, to send the patient to an ear specialist of her own choosing. She returned with a story of his having taken undue liberties with her. I told her there was no need now for her to see him again. But she did go back twice, each time coming to me with the same story. I thought then that considering the character of the incidents related, her reactions were excessive. Long afterward when the analysis was practically over, she told me that there was no truth in her stories about the man.

In this instance transference probably accounted for her tales. She had no interest in the other physician and ceased to return to him as soon as she saw that I paid no attention to her complaints.

About eighteen months ago a patient was referred to me by the president of the board of directors of a missionary society. She was brought to Cincinnati accompanied by a physician from the missionary station in South America where she had been serving as a teacher and nurse in a hospital, with a history of a severe attack of hysterical confusion. It was even implied that she was insane. I could secure from her physician only a vague and indefinite history. He had seen her only once or twice during her attacks and noted nothing unusual in her conduct on the long journey from Lima to Cincinnati. She was said to have displayed great sexual excitement and to have told many contradictory stories. Her physician spoke of the case as one of nymphomania.

The patient, M. B., was thirty-one and single. The physical examination was negative. She was quiet in demeanor, and apparently phlegmatic in temperament. Certainly not of an evidently nervous type. She was eager to understand the motivation of certain peculiarities she had shown during her life and hence cooperated in our work.

Prior to the attack that was the occasion of her return to the United States, she had done well as a missionary and felt that she had enjoyed her work. Her memory for the whole attack was quite clear, and she was able to give me a complete account of all of her words and actions, her motives only remaining obscure to her.

Miss B.'s station consisted of a hospital manned by three physicians and several young women, of whom the patient was one, who acted as nurses. All were from the United States.

One week before the episode of excitement, Miss B. told the other girls of a letter she had just received from Mrs. A. of Cincinnati who was president of the missionary board. This letter, she said, demanded that she explain certain events of her past life, implying that her past reputation was being questioned. This was one of certain characteristic preliminary remarks casually made that often preceded prior confessions she had made in her life. Its purpose was evidently to excite interest and pave the way for further revelations. A week later she showed signs of great distress while writing a letter. This also excited interest on the part of the other girls. She pretended that the contents of the letter had to be kept a deep secret. The next morning at breakfast she appeared to be depressed and to be having difficulty in keeping back the tears. To their questions she said that she had received a letter about her father that worried her greatly. Later in the day she elaborated this story. She said that her father had seduced a young girl and that the girl's mother had written her, the patient, stating that she must finance this girl, who was supposed to be pregnant, to save her father from further trouble. This story was highly detailed and circumstantial. It was apparently spontaneous and sincere but she said, in relating the tale to me, that the night before as she lay awake it had gradually been taking form in her mind. "It came out contrary," she said, "to my resolution not to tell such stories." But she was not conscious of any motive.

The following day she transferred her story to experiences involving her own past life. She told of visits she had made to a cabaret in Cleveland. The expression *cabaret* here was merely a synonym for house of prostitution. The meaning of this we shall see later. With great detail and apparent sincerity she told the girls of fantastic and obscene revels that she saw there. This account seems

to have created the sensation that she wished for, and the next afternoon she still further elaborated her story. Many of these details it will be necessary to omit, but she said she had visited this place eight or nine times over as many week ends. In her story her escort importunes her to submit to him and beats her about the genitals, causing great swelling so that she is unable to walk. Finally she admitted to having had intercourse with him and three other men.

All of this fantastic tale was sheer invention. She confessed to a constant and intense sexual desire and asked the other girls to protect her from giving away to this desire. For two nights she forced one or more of them to sit beside her bed and hold her hands to prevent masturbation. She threw herself about the bed in hysterical convulsions, all the time reiterating expressions of desire and lamenting her past experiences. She sent them to search for a bottle of carbolic acid that she had hidden in her coat pocket but all the time, she states, she had not the slightest intention of committing suicide. Even her expressions of passion and desire were highly exaggerated. She was clearly conscious during the whole time that the whole affair was merely a dramatization and an elaborate lie. In the actual presence of men she was never conscious of any sexual desire whatever. Even her statements about her desire to masturbate were highly exaggerated. She had masturbated at intervals during her life, but in very moderate degree.

Finally a physician was called who gave her some sedatives. She was kept in bed, and a few days later began to retract her story saying that it was only partially true. Later she admitted that it had no basis of truth whatever. But by this time her conduct and actions caused those in authority to decide that it was wiser for her to return to the United States, as previously noted.

When I undertook to investigate the incidents preceding this hysterical episode, I found the following remarkable occurrence: Three weeks previously to the first of the attacks, a girl, one of her associates at the missionary station, went walking with a young man along a lonely stretch of beach. Meeting eight soldiers, the girl's escort was seized and bound to a tree while before his eyes the girl was thrown to the ground and held by some while all the soldiers in turn criminally assaulted her. This girl was not permanently injured but was confined to her bed some days under the care, principally, of Miss B. The genitals were swollen and for a time she was unable to walk. This was one of several elements in this tragic episode that furnished material for the patient's prostitution fantasy.

Miss B. said to this girl when she was relating how she attempted to guard her body, "I wish it had been me." When the girl, surprised, asked her why, she said, "Because I have not always been so successful in guarding my body." This was the first of the casual allusions that finally developed into her remarkable confessions.

Miss B. came from a middle class family in northern Ohio. Her father was of a peculiarly stubborn and illtempered disposition, but rather religious and with many fantastic ideas. Her mother was apparently unhappy and was released of her burdens by death when the patient was seven years of age. A year later the father married a neighbor woman, bringing some half brothers and sisters into the family. All the time the father seemed to bear the patient, of all the children, some especial grudge. He appeared to single her out for ill treatment and excessive demands. Nothing she did—and she tried hard to please him—could satisfy him. At once instance, she never did her work well enough and her grades at school were never high enough to satisfy him. His attitude was evidently a defense. One evening after some unhappy episode with her father she went out on the porch and, looking up at the stars, said, "If you don't care for me any more than this, God, then I don't care for you." She often repeated this remark in later years when in any difficulty.

But the remark caused her to think later that she might have committed the unpardonable sin, which worried her for some time. At about the age of ten, three boys and one other, her brother, took her to the barn and had intercourse with her. It will be recalled that this was the number of men mentioned in her prostitution fantasy,—three and one other, her escort. This episode appeared to leave no ill effect and she seemed to have enjoyed for the most part a fairly normal childhood. She was, however, considered very much of a tomboy. On some occasions she indulged in sexual play with her brother or other girls. Between the ages of twelve and sixteen she became profoundly religious and underwent the usual adolescent religious doubts and experiences. At this time she conceived the idea of being a missionary. This idea was evidently motivated largely by the idea of escape. Also at about fifteen or sixteen she often thought of running away and becoming a prostitute. Indeed she stated that between this age and the age when she actually entered the missionary training school she had frequent doubts as to whether she should become a missionary or a prostitute.

At about her fifteenth year she confessed to a friend a mad craving for liquor. She actually had no such craving but enjoyed her friend's shocked attitude. Several times about this time she confessed to such a desire and also to wishing to smoke cigarettes, her naïve symbols for devilishness. She describes this period of longing and religious doubts as a real storm and stress period of her life. "Sometimes I thought I was a Christian, sometimes not. Sometimes I believed in God, sometimes not." During her last year in high school she once stayed after school in apparent distress of mind. On her teacher's asking her the trouble, she told her that a certain married man in the neighborhood was molesting her. That she had been out with him several times and that he pursued her with unwelcome attentions. All the time, she states, she knew that there was not a word of truth in the statement." Some days later she repeated the same confession and permitted her teacher to infer from her lack of response to direct questions that she had had intercourse with this man. She then asked the teacher to get a bottle of carbolic acid from her coat pocket. This the teacher found, but all the time she had had no intention of committing suicide. Again she even one evening stopped at her teacher's home, told her

that she was being followed by this man and begged her to escort her home. Both of these elements, it will be recalled, were repeated in her adult attack.

All during this period she suffered from despondency, although as she says, "I don't really think I was as despondent as I seemed to others." Due to her father's bitter opposition even to the most brief and innocent association with a boy, until she was nineteen she had no male friends whatever. A brief interest at this age was broken up because of her father's violent threats against the young man.

When twenty, Miss B. went to a neighboring city and began to teach, living with an aunt. Here she attended the Baptist church merely because the teacher to whom she had made her first confession was a Baptist. Among her new friends, she posed as having had a past, having drank and smoked and implied worse things, so to speak. She returned home in the summer and found life with her father more intolerable than ever. She now returned again to this town, living now with a friend, and taught country school there for five years. During this time she told to three different women friends a tale of being engaged to a young man who was a drunkard, and said that this stood in the way of her marriage. She was always, of course, advised against marrying. There was no truth in this tale. To one of these women friends she also confessed a desire to drink, smoke and play cards. She also told this woman the seduction tale referring to her father. The woman was much shocked. She spent the night with her and for hours moaned and sobbed, complaining of the difficulty she had in keeping virtuous. This was also not true, as she had but little interest in men. Finally she begged her to have "immoral relations" with her, as she expressed it in her biographical sketch. To one of the other girls to whom she made the same false confessions she also made frequent and violent erotic advances, always ending by begging her to enter into a homosexual relationship with her. In no instance were her advances reciprocated. During this period in two instances, young men whom she met casually attempted intercourse. This came to nothing. She was not much interested and resisted through fear of consequences. She never saw them again. She took to moderate masturbation, carrying it out in ways she had heard described by a Y. W. C. A. lecturer who said that it would drive one insane. Before this she states she knew nothing about it. Her autoerotic fancies concerned her girl friends. She was also quite narcissistic, being fond of posing nude before the mirror. Her masturbation was of the aggressive type, as she made use of objects external to herself, such as a blanket or a chair.

During this period of her life she carried out the following strange dramatization: She said that she had put her foot through a hole in a rotten plank on the school porch and injured it. She stayed in bed a week, rested her foot on a chair for another week and walked on crutches for some time. Even in after years she often referred to her bad foot. The school board paid her salary, that of a substitute teacher, and her doctor's bill. She was at the time unaware of any motive for this deception. On other occasions previously she had indulged in malingering, once purposely burning her hand in the chemical laboratory.

Finally she entered a missionary training school. Here, too, she confessed to a teacher of a craving for alcohol. She also confessed to this teacher, a woman, that she was greatly troubled because she had learned that her father had seduced a young girl. This was the second time that the young girl seduction confession involved her father. The following summer she confessed to another girl student of a craving for drink, for selfabuse and of relations with a married man when she was sixteen. She appeared nervous and excited. She was put to bed in a hospital and a woman physician sent for. This physician dilated the cervix and amputated the clitoris. The patient now had frequent attacks of feigned unconsciousness during which she used profane and obscene expressions. It occurred to her that she ought to run away and find a man, but she compromised by smoking cigarettes.

She had one or two further erotic crises with accompanying confessions. After she had concluded her missionary training school courses she became engaged to a theological student who was intending to go to India as a missionary. This was in the spring of 1921. He wanted her to marry him immediately but as he had four more years to study, this she refused to do. By autumn of that year he was engaged to another girl and the patient left for South America, where two years later the hysterical attack already described, which resulted in her return to the United States, ensued. The breaking of her engagement to the theological student left her quite unmoved and she was apparently indifferent when she received a letter from him stating that he was about to marry the other girl. Her relation to this man had no erotic quality whatever.

Before she left Lima and as she told the other girls that the stories she had told them of her cabaret experiences were not true, they remarked that they could hardly believe this, as in the telling all her emotional expressions had seemed so deep and genuine. In every instance where she had made a confession, she wrote to the woman confessed to, months and sometimes years afterwards, admitting the falseness of her statements.

Her missionary attempt thus had to be given up. As either a prostitute or a missionary she would not have been, was not, successful. Both are essentially artificial, in most cases being merely attempts at escape from reality, the outgrowth, in many instances, of an emotionally starved childhood. Yet she might just as easily have become a prostitute as a missionary. However, such qualities of her character as made her a good missionary would have interfered with her becoming a successful prostitute and on the other hand her prostitution fancies ended her life as a missionary. A craving for sharply contrasting pathways in life generally means that neither is best for the individual.

It will be noted that she fluctuated between affirming and denying God, between good and bad, between male and female, and between sadistic and maschochistic attitudes. The malingering episode probably had a symbolic meaning. The meaning of the frequent tale of father and young girl seduction

is sufficiently clear. The confessions per se were in some degree modes of homosexual aggression but at the same time, their content being heterosexual in character, they undoubtedly expressed such impulses extending far back to childhood. The patient became clearly conscious of her divergent impulses, the later homosexual overlying the earlier heterosexual, a reversal of the usual order of development. The rape brought so vividly to her attention activated associational systems surrounding the childhood episode of a similar character. Her hysterical attack was thus in the nature of an abreaction to that earliest episode, symbolically expressed.

Because of this and other reasons, her relation to her father, principally, the pathway to a normal heterosexual development was blocked. Her homosexual gropings might then be regarded as attempts to return symbolically to the father as represented by their details of expression, but principally to the mother as represented by their objects. In times of stress the neurotic will often show in some degree the flight back to the mother image. The deepest wish is again to become identified with the mother, as is the child in the womb. In this case the mother image was sought in the women confessed to. In many instances they occupied a motherlike relation to the patient.

In this connection it is interesting to recall that it is to the mother we all first confess. Thus also in passing I may observe the confession element in the analysis may tend to favor the identification by the patient of the physician with the mother, elements of which identification may sometimes be observed. Finally, one may ask oneself, to what extent does the search for the mother, the attempt to return to the mother, or the identification of other women with the mother explain homosexuality in women?

Miss B. was advised to give up her missionary ambitions. She went to northern Ohio and again began to teach. A year later I received a letter from her in which she said that she was building a new and happier life for herself.

The Psychopathic Child*

SANGER BROWN, 2nd, M.D.
New York

The psychopathic child has been the subject of much comment in recent years. One hears of him in schools, clinics and institutions. In discussing him it may be well to arrive at a definition as to what sort of being he is.

The word psychopathic may or may not be a fortunate term. It came into use first through psychiatry, applied to the mentally unstable, and at times to the morally unreliable adult. The word constitutional is often linked with psychopathic, suggesting that psychopathic conditions are inherent. In psychiatric classifications the following conditions are classified under constitutional psychopathic states: emotional instability, inadequate personality, nomadism, paranoid personality, pathological liar, sexual psychopathy, alcoholism, drug addiction, and criminalism. If we use the term psychopathic in speaking of children, we must appreciate that it is going to have a somewhat damning significance. Granting this fact, however, we must admit that one sees many unstable neurotic, delinquent children, for whom some term must be used. With these qualifications we may discuss the socalled psychopathic child. In the course of discussion it may be possible to define his symptoms in such a way that the term psychopathic will be used only when it applies.

One sees many different kinds of children in this socalled psychopathic group. In New York city last year, over a thousand children were taken to the children's courts charged with varying delinquencies. These children might perhaps all be called psychopathic, but they fall into several different groups, and so this somewhat too comprehensive term may be restricted.

*Read before the American Association for the Study of the Feebleminded, June 2, 1924. Washington, D. C.

To begin with, we must place the mentally defective in a separate group. Mentally defective children of course may show emotional instability as well, but in any case the mentally defective children should be classified in a separate group, possibly with specially descriptive terms for those who have emotional instability.

The second group which may be separated from the others are children with nervous symptoms. They form a large percentage of the socalled psychopathic group. Thanks to studies during recent years, we can recognize these nervous cases quite definitely. They are unstable emotionally, they are subject to outbursts of temper, they sleep poorly, they have fears, and a certain number of them have compulsions and phobias. As a result of this emotional instability they have a number of accompanying physical symptoms familiar to everyone, such as nail biting, twitching of the face, overactivity, batting of the eyes, stammering, and other symptoms.

Now these and many others are all symptoms with which we are familiar. With adults the condition is termed a psychoneurosis. These symptoms in children are one and the same thing, but it seems best to speak of them as nervous children, rather than psychoneurotics, as the latter term seems a rather serious term with which to label a child.

The causes of these nervous conditions are now quite well understood. From the psychological viewpoint they are the result of failure in school, troubles at home, bad environment; and from the physical point of view they may follow injuries, diseases, and poor health.

These nervous children are likely to become psychopathic; i. e., to show varying degrees of delinquency and disorders of conduct, and so, while

they are frequently seen in clinics and are regarded as psychopathic children, it must be remembered that they belong to a well defined group of nervous children and are psychopathic only secondarily.

Another type of child which should not be termed psychopathic at all, but often is so designated, is the dull child; he who, by intelligence tests, has a rating of between eighty or ninety or thereabouts. Such a child is seldom properly classified in school. He comes in for more or less discipline and punishment and he is apt to be a failure. It is easy to see how such a child becomes unstable. Many of the socalled problem cases are of this dull group, and the problem would be solved if there was some special provision for them in the school. In any case a fair number of them become delinquent but the difficulty with them is not a psychopathic state, but dull intelligence.

Other groups may be considered from the physical viewpoint. These are the glandular or endocrine cases. Dismissing all extravagant talk about the relationship between glands and personality, the fact remains that a certain percentage of children show endocrine disorders accompanied by mental instability of one type or another. For example, the child with pituitary disorders, who is greatly overweight, with infantile sex organs and with body contour of the female type, is not infrequently backward mentally. Again, the very tall child, with thin tapering fingers and narrow pelvis and with evidences of glandular imbalance in which the thymus gland is involved, is not only inferior physically but may be neurotic, and possibly backward in mental development. Conditions where there is lack of energy and with low blood pressure are associated with inactivity of the suprarenal glands. Other more familiar types, such as thyroid disturbances, are well known. These glandular cases are all handicapped in one way or another. Besides physical disabilities they have mental disabilities too, and are likely to be termed psychopathic.

In the physical sphere, aside from the glandular cases, there are of course, those who have physical defects. In New York city one sees a fair number of subjects who have had head injuries from accidents. Emotional instability of many months' duration may follow such an accident. Cases following meningitis as well as scarlet fever or measles, often present nervous symptoms for some months, such as restlessness, stuttering and enuresis.

The nervous instability following lethargic encephalitis in children is now well recognized. These superficially appear like psychopathic children, but of course the condition is the result of the disease.

Another group found among these socalled psychopathic cases are children who seem practically normal in every way as far as their intelligence and their nervous stability are concerned, but who have been subjected to an unfavorable environment for years, so that they have become quite abnormal mentally in many respects. If we are to call them psychopathic we must realize that the condition is not inherent and that it may be remedied.

Relatives and teachers sometimes ask if nervous symptoms and delinquency are early signs of insanity. Insanity does occasionally occur in children, but it is very rare and it is not possible to recognize symptoms of beginning insanity under the age of twelve as a rule, and so we can generally reassure parents in this respect.

Convulsions and certain mild forms of epilepsy are frequent in the general population, as shown by census reports. This condition is often unrecognized during childhood. The child may be called psychopathic when in reality he is suffering from epilepsy.

From what has been said and much more that might be said, it should be clear that the term psychopathic should be used very guardedly. Scientifically, the following types cannot be called primarily psychopathic, although they may have psychopathic symptoms: 1. Mental defectives. 2. Nervous children. 3. Endocrine cases. 4. Children with dull intelligence. 5. Children mentally unstable, resulting from physical defects. 6. Cases resulting from poor environment.

If we are to use the term psychopathic, therefore, as applied to children, we must realize that we are not talking about the same condition as psychiatrists mean when they speak of a psychopathic state in an adult. Possibly these nervous conditions and bad environmental conditions and physical defects, handicap the developing child in such a way that he may indeed become psychopathic in later years. Certainly those who have had experience in schools and clinics see young people to whom such a term is applicable. One suggestion would be, therefore, to use the term psychopathic as applicable only to adolescents and adults, and not children, using a more descriptive term for the latter.

In any case, it is interesting to see the soil from which the adult psychopaths may develop. They develop from conditions which are recognizable during childhood and possibly avoidable. One of the conditions may be low intelligence, for example, although this is not the rule since many people with low intelligence are not at all psychopathic. Nervous instability, bad environment, inappropriate education during childhood, are factors, as are numerous other mental and physical causes, as has been indicated.

In any case, it should be quite evident that a very complete survey is necessary in order to recognize these prepsychopathic states, if such a term may be used. This examination should include a thorough physical survey, not only in respect to physical defects but also body growth and endocrine status. The entire psychology of the child should be investigated in respect to his emotional control, his intelligence, environmental and family influences, and his school status. Preventive measures may be very effective at this time of life if the underlying causes of the difficulty are recognized.

In concluding, it may be stated again that we should be quite careful in the use of this term psychopathic. Before the age of twelve, children are easily moulded, dependent upon the influences which are brought to bear upon them. While certain mental traits, of course, may be inherited, even these may be greatly modified and the child may be guided in such a way as to overcome undesirable qualities. Any diagnosis, therefore, which carries with it an unfavorable prognosis, should be avoided. Teachers, physicians, and parents, if they are to accomplish results with these particular children, must appreciate the fact that the problems of each may be solved

through scientific understanding. It must be appreciated that what has been termed human nature can be greatly modified by a number of influences, and that facts have been accumulated in the study of the psychology of children during the past two decades which have pointed the direction for preventive measures in the future. Often the solution of the problem lies with the school, and fortunately, schools can be found today, both private and public, where the unstable child receives understanding and scientific attention.

173 East Seventieth Street.

Encephalitic Features of the 1921-22 Epidemic Influenza*

LODOVICO MONCALVI, M.D.
Milan, Italy

Certain peculiarities noticed in the course of the influenza epidemic which appeared recently in Milan and elsewhere, induced someone to express a doubt as to its identity with common influenza. Yet, as this disease is recognizable only through clinical and epidemiological characters which are prone to vary according to the place, season and individual substratum wherein the disease originates and develops, I think a doubt is not consistent which is grounded only on symptomatological differences referable to the natural polymorphism of the epidemic.

During the recent epidemic influenza's classical symptoms were present, namely, acute rhinopharyngeal catarrh, with or without conjunctivitis, headache, high fever for one to three days, followed by a severe asthenia wholly disproportionate to the degree and duration of the infectious attack. Frequently there was tracheolaryngitis characterized by local itching, hoarseness and dry, spasmodic cough; also frequently gastrointestinal troubles, such as anorexia, dyspepsia, and constipation. But I have seen many other cases in which the catarrhal phenomena of the upper air passages were absent or trifling, while, on the contrary, the general phenomena were very pronounced, such as fever, malaise, prostration and so on (simple influenzal fever, typhoid influenza). In these cases the fever was quite different in character and lasted from one to eight days, sometimes longer; the average temperature was about 38° C. Some cases began with moderate fever, which went higher and higher until it reached 40° C., as in the first week of a regular typhus, and afterwards it dropped quickly to apyrexia.

Other cases ran an inverse course, beginning with high fever and coming to apyrexia through lower and lower temperatures. The tendency to relapse was very noticeable, especially in these latter cases which presented no catarrhal phenomena. The relapse generally occurred two or three days after the end of the first attack, appearing almost as a second phase of the sickness.

These varying manifestations of influenza, however, are neither strange nor unusual, since they were already observed and described during the European epidemic of the years 1889-90, and were again noticed during the great pandemic of 1917-20. As for the bronchopneumonic and pleuritic complications, their character and frequency were proportionate to the importance of the present epidemic, which is, in many respects, comparable to that of 1890.

Most noticeable were the neuroencephalitic forms of the disease, not only on account of their clinical interest, but also because of their identity with the manifestations of the disease during the epidemic of 1918-20, which had brought out the idea of a new and uncommon disease—encephalitis lethargica.

I shall not speak of the numerous neuralgic forms, especially of the trigeminus and cervical plexus, which only indicate, through their frequency, the neurotropic character of the present influenzal virus, and forms, as it were, an epidemic frame wherein the profound and complex nervous localizations are settled. I remember that the monosymptomatic sobbing lately reappeared in many places of our province. It was so strictly connected with the epidemic that its influenzal genesis could not be denied.

I have observed several cases recently which presented a cerebral symptomatology closely resembling epidemic encephalitis.[1]

In these cases we had to do with typical encephalitic types, not very severe (a single case came afterwards to death). Their identity with those we have observed since 1918 is complete under all circumstances. Moreover, I was informed by several colleagues that other cases like these were meantime noticed in Milan and in its province during the late influenzal epidemic.

Such cases as these which I encountered demonstrated clearly the intimate relationship existing between influenza and epidemic encephalitis which must rightly be considered as a form of influenzal encephalitis. The fact that in epidemic encephalitis a foregoing phase of catarrhal influenza is not always recognizable, cannot weaken the evidence of all the other manifestations, and can, in addition, be easily explained with what we know about the manifold clinical features of influenza and especially about its primary noncatarrhal forms. Perhaps the insufficiency or the lack of topical and general reaction phenomena is rather favorable toward the localization of the influenzal virus in the nervous system.

This reappearance of the well known encephalitic forms in the present epidemic, indicates the historical continuance of the conception according to which encephalitis lethargica or epidemica is but a nosographical contemporary feature of what was formerly called nervous influenza. In connection herewith a publication of Dr. Kayser-Petersen, of Frankfurt (2) is noteworthy which, although later than the Italian authors, such as Monti, Bignami, Tarozzi, Modena, etc., aids in clearing the question of the identity between nervous influenza and encephalitis epidemica.

*From a paper read at the Soc. Lomb. di Scienze medicobiologiche, March 10, 1922.

[1]The histories of these cases will be included in the author's reprints. They have been omitted for lack of space.

The Islets of Langerhans and the Functions of the Pancreas

SWALE VINCENT, LL.D., D.Sc., M.D., F.R.S. (Edin.), F.R.S. (Can.), M.R.C.S., L.R.C.P., F.Z.S.

London

Professor of Physiology in the University of London (Middlesex Hospital Medical School)

INTRODUCTION

The cell islets first described by Langerhans (16) in 1869 began to attract attention after the discovery by von Mering and Minkowski (20) that extirpation of the pancreas in animals gives rise to a condition which is in many cases indistinguishable from diabetes in the human subject. With the growth of the doctrine of internal secretion as applied to many organs of the body it was inevitable that the islets should be credited with the function of internal secretion, as they possess no ducts leading to the exterior and the function of the rest of the pancreas was well understood. In 1895 Schäfer (30a) suggested that the islets furnish some internal secretion possessing the power of maintaining the carbohydrate balance of the blood, and in his monograph (30b) published in 1916 the same author remarked that "Provisionally it will be convenient to refer to this hypothetical autacoid as *insuline*." Since then there has been an increasing tendency to regard the islets as organs *sui generis*, totally separate and distinct from the zymogenous tubules of the pancreas, and carrying out the internally secreting function of the pancreas. It may be found that the islet tissue is in fact endowed with the power of internal secretion, but as we shall see there is yet no proof of this, and it seems clear that the structures in question are not essentially different in origin or fundamental structure from the externally secreting acini.

HISTORY

There is no need to record the history of the subject in any detail. This has been done on several occasions and reference to the bibliography accompanying this article will enable the reader to obtain a fairly complete story of the subject.

Writers may be divided into two chief groups according to their views as to the morphological significance of the islets. The first of these includes those who believe that the islets are essentially of the same embryological and morphological nature as the zymogenous tubules and are not to be looked upon as in any sense organs *sui generis*. The second group of observers is constituted by those who regard the structures in question as definite and distinct organs, analogous to the cortex of the adrenal body, the epithelial part of the pituitary, and the parathyroids, and consider that they have no connection (except perhaps a community of embryonic origin) with the secreting tubules of the pancreas.

Kohn (11) classifies the islets as one of his *"Drüsen ohne Ausführungsgang—ohne Drüsenlumen"* (*"corpora glanduliformia"*) along with the parathyroids, epithelial pituitary, and the adrenal cortex. Some among the older workers in the first group even considered that there may be no difference in *function* between the islets and the rest of the pancreas. Thus Harris and Gow (8) thought that the islets might take part in the external secretion, probably forming one of the ferments. Jarotzky (10) believed that they may take part both in an internal and an external secretion. Lewaschen (17) and Pischinger (25) looked upon the islets as exhausted secreting cavities, and thought that after a period of repose they may again take on their secretory function. Tschassowinkow (33) and Dogiel (5) on the contrary have expressed the opinion that the islets are exhausted acini which are unable to return to their former state of activity. Statkewitsch (32) looks upon islets as alveoli modified by inanition, and Mankowsky (19) emphasizes the intimate relation subsisting between islets and tubules, their functional variations and forms of transition.

In most vertebrates there are no lumina in the islets of Langerhans. But Gianelli and Giacomini (7) described lumina in the reptilian islets and their existence has been confirmed by Laguesse (12) and others. The last named observer refuses to admit that the islets are simply masses of exhausted acini, and thinks that they are temporarily modified for the purpose of supplying an internal secretion.

The authors belonging to the second chief group all believe in the "internal secretion" theory of the islets, and indeed so convinced are many of them that this is the true theory, that they refuse to admit the occurrence of changes in the islet in exhaustion and inanition and the transition forms from one kind of tissue to the other. The chief upholders of this

"separate organ" view of the islets are Diamare (4), Rennie (28) and Helly (9) among comparative anatomists and Ssobolen (31), Opie (24), Weichselbaum (39) and others among pathologists.

Rennie (28) in his work upon teleostean fishes, describes the fairly constant occurrence of an encapsulated islet ("principal islet") of large size, whose relation to the main part of the pancreatic seems to be slight. He considers the islets to be "blood glands which have entered into a secondary relation to the pancreas" and finds no transitional forms.

MORE RECENT INVESTIGATIONS

In the year 1904 Dale (3) reported that an increase in the amount of islet tissue may be induced by exhausting the pancreas by means of secretion. This announcement induced the present writer in conjunction with Mrs. F. D. Thompson (34, 35) to investigate the comparative anatomy and physiology of the islets in different classes of animals. Our studies included an investigation into the normal structure of the pancreas in the following animals:

Mammals.—Dog, cat, badger, ox, rabbit, guinea-pig, chipmunk, mouse, bat.

Birds.—Pigeon, duck, sparrow.

Reptiles.—Chrysemys picta, kinosternon pennsylvanicum.

Amphibians.—Rana temporaria (esculenta?), Plethodon glutinosus.

Fishes.—Teleostei, Amiurus vulgaris, A. nigricans, Catostomus teres, Hyodon alosoides, Stizostedium vitreum, S. canadense, Moxostoma aureolum, Esox lucius.

Ganoidei.—Acipenser rubicundus, Amia calva

We found that in all the chief groups of vertebrates the islets frequently show distinct traces of an alveolar arrangement. The solid columns composing the islet often show, for example, a double row of nuclei corresponding to the position of the nuclei in the secreting tubules. The islet columns are frequently in complete anatomical continuity with the surrounding zymogenous tubules and all kinds of transition forms are common throughout vertebrates. In reptiles and fishes a distinct lumen within the islet area can sometimes be detected.

In two further communications (36, 37) the results of an examination of the following species were given:

Reptiles.—Testuolo tabulata, Lacerta viridis, Tropidonotas natrix, Coluber longissimus.

Elasmobranchs.—Scyllium canicula, Acanthices vulgaris, Mustelus laevis, Rhina squatina, Raja clavata, Raja circularis.

In the reptiles the islets are not always very striking and may consist of merely a few cells. Transition forms between islet and alveoli are fairly common and the former are frequently in close contiguity to the ducts, reminding one of the arrangement in the elasmobranchs.

In elasmobranchs the islets are sometimes of the mammalian type, sometimes more primitive and closely related to the ducts. For a fuller description (with colored illustrations) the reader is referred to our original paper (37).

The effects of inanition and administration of secretion will be referred to later.

Bensley (1) in 1911 published a paper on the structure of the pancreas. In this he states that he arrived at very different results from those of Vincent and Thompson. Bensley's work was very painstaking and his conclusions seem to have been very generally accepted, with the result that the majority of authors who have no first hand information on the subject believe in the "separate organ" theory of the islets.

A communication by Lane (15) had appeared in the year 1907. In this special attention was called to two different kinds of cells within the islet. These had been noticed by previous observers, but Lane laid special stress on certain "specific" granules occurring in each kind of cell, which, he thought, enabled him to distinguish not only each of these kinds of cells from the other, but both kinds from zymogenous tissue.

Since the appearance of Bensley's communication Laguesse (13, 14) and Saguchi (29) and others from the standpoint of comparative anatomy have strongly supported the views put forward by Mrs. Thompson and myself.

STRUCTURE OF THE ISLETS

Some years ago I carried out (in conjunction with J. P. Parsons) an investigation on the islets of Langerhans using the histological methods of Lane and Bensley, and saw no reasons for changing my views. Bensley's communication contained the results of so much painstaking investigation carried out by methods which differed in many respects from those employed by Vincent and Thompson, that at the outset we were impressed with the possibility that a renewed inquiry might compel us to agree with his conclusions. But the sequel has proved the contrary. I am now more than ever convinced that Bensley did not arrive at the correct result.

The important points to be discussed are: 1, The anatomical relationship between islet and acinus; 2. the specific nature of the islet cell (and its contents).

The question as to continuity between islet and zymogenous tubules need hardly be discussed, since Bensley admits that such may and frequently does exist. It has been shown by Vincent and Thompson to be a common occurrence in the lower vertebrates. A trace of a lumen in the islet tissue is also frequently to be found.

But Bensley, and others who agree with him, insist that the islet cells constitute a double histological entity, and that each of the two kinds of islet cell is distinguished from the zymogenous cells by absolutely characteristic cytological features, that is to say, by the possession of specific granules reacting to particular stains. In other words, although the zymogenous tubules may appear to run into the islet tissue, there is in reality a sudden change when we pass from a zymogenous cell to an islet cell; since the latter contains none of the specific contents of the former and possesses for its part specific granules peculiar to itself.

On the question of continuity between acini and islets Bensley's attitude is not consistent. On p. 352 of his paper he says: "The examination of preparations . . . shows that the apparent continuity between islets and acini or ducts is real," but on p. 376 occurs a passage which seems to indicate that

he thinks that this apparent continuity is due to the shape of the islet and the direction of the section.

The author in question lays great stress upon the existence of absolutely specific granules in the islet cells, and would not admit the claim of any cell to rank as an islet cell unless it contain such granules. I am of opinion that the specific nature of the A and B granules has not been proved. Using the Lane B method with material from the guineapig it may be admitted that the histological picture corresponds fairly well with what Lane and Bensley describe; the B cells appear violet due to the presence of violet stained granules, and the A cells are faintly colored with the orange G. Employing Lane's method for the A cells, it is not always easy to mark their limits, and their nuclei do not appear to differ in shape from those of the B cells. Moreover, the A and B cells do not come out as clearly as one would expect after reading the descriptions of Lane and Bensley. Sometimes it is even difficult to say whether a particular deeply stained cell is to be put in the A or in the B category; the tint is sometimes brownish mixed with violet or vice versa. In many cases only part of the cell is stained, in other cases one part of the cell stains more deeply than another. Thus the A cells (Lane's method) may be deep violet in one part and the color may fade away so that the other end of the cell resembles in tint the almost unstained surrounding B cells. It is thus by no means clear that we have to deal with two different types of cell. It seems possible that there are various stages of activity revealed by differences in staining reaction.

I am convinced that the acinous cells contain granules which give staining reactions very similar to those of some of the B cells of the islet, and if Bensley's acid fuchsin-methyl green method be employed, we find scattered throughout the pancreas certain zymogenous cells which come out a deep red while others are green.

Bensley insists, that, in order to prove the existence of true transitions between acinous and islet cells, some cells must be shown to contain both zymogenous granules (or other specific granules belonging to the acinous cells) and specific islet granules. He discusses at some length the significance of the socalled Mankowski granules in the zymogenous cells and comes to the conclusion that these are something quite different from the specific islet granules. In this he may be correct, but I believe that I have seen certain granules within the cells of the zymogenous tubules which are at any rate not very different in regard to size and staining reaction from some of those found in certain islet cells.

Further, it cannot be allowed that the criterion for "transition" above referred to, should be insisted upon. We can conceive that a real transition between the two kinds of cells might manifest itself in a somewhat different way. The number of zymogenous granules in the acinous cells might become gradually reduced as one approaches the edge of an islet, until at a certain point the cells are found to contain no such granules. Careful examination of these might then reveal the presence of granules which are stained by the "specific" reagents for islet tissue. Thus, there might be a certain degree of suddenness in the occurrence of the specific granules, though the total change might reasonably be regarded as a real transition from one tissue to the other. This seems all the more plausible in view of the anatomical continuity which is admitted to occur in some cases. On the other hand it may be noted that the islets of Langerhans are surrounded at a little distance by a zone of zymogenous tissue which stains more deeply than the rest of the gland. This observation is very suggestive of the possibility that the islets may, after all, have some function in relation to the zymogenous function of the pancreas.

Vincent and Thompson studied the effects of inanition in the dog, cat, pigeon, and frog, and reported that in these animals the effect is markedly to increase the amount of islet tissue at the expense of the zymogenous. These results, so far as concerns the bird, were confirmed by Laguesse. More recently Parsons and myself carried out inanition experiments upon the rat, gopher, guineapig and hen, and repeated the experiments upon the cat and the frog. The results were entirely confirmatory of those of Vincent and Thompson. Bensley working with the guineapig, has been unable to observe any increase in islets after inanition, and offers some criticism of the work of Vincent and Thompson. One obvious criticism of this work has recently occurred to me, though it has escaped Bensley's notice. Even assuming that the islet tissue be unaltered in amount, since the whole pancreas shrinks during inanition, there will be an apparent proportionate increase in the amount of islet tissue in any given portion of the gland. In the majority of animals the pancreas shrinks to about half its original bulk after ten or twelve days' inanition; so that in order to justify the statement that the islet tissue is actually increased in amount the apparent increase should make the islets more than double their original size. In the majority of instances we have found this to be actually the case.

Bensley objects that by the method of calculation employed, the increase in islet tissue which Vincent and Thompson thought they observed, was possibly accounted for by the normal variation which occurs. If this were the case, it might surely happen in many instances that the mistake might be in the opposite direction, and that the impression gained by looking over a parallel series of slides (of normal and inanition preparations respectively) might be that the islet tissue is frequently reduced by inanition. This we never observed. In the more recent experiments we have used the planimeter and have ascertained by this means the limits of normal variation as well as the amount of increase after a period of inanition.

So far as I can ascertain, Bensley does not appear to have reckoned with the *amount* of islet tissue under any conditions. By his neutral red method he has counted, it is true, the *number* of islets under varying conditions and states that this number is fairly constant. Now the important point is the actual amount of islet tissue, irrespective of the number of islets which make it up. Three or four large islets might easily represent a vast increase in islet tissue over a score of small ones. We imagine, indeed, that what happens in the majority of cases is that the very small islets consisting only of a few cells are increased enormously during inanition. Bensley's method was incapable of revealing such a change.

The following may be taken as an example of the result of a careful estimate of the actual variation under normal conditions in the amount of islet tissue in the pancreas of the hen. Slides of mounted serial sections were taken at random and the area of islet tissue was measured in three or four sections in different parts of each slide. The material was taken from different parts of the gland. Fifty fields were examined. The area varied from 0.035 units to 0.580 units. The average area amounted to 0.346 units.

In the pancreas of a hen after twelve days' inanition the area of islet tissue varied from 0.230 units to 1.590 units. The average amounted to 0.822 units. Thus, in the inanition pancreas there was 3.34 times as much islet tissue as in the normal.

EFFECTS OF OTHER CHANGES OF CONDITIONS ON THE AMOUNT OF ISLET TISSUE

In rats a pure carbohydrate diet markedly increases the amount of islet tissue, while a pure protein diet either leaves the amount at the normal level, or even somewhat diminishes it.

Extirpation of the spleen increases the amount of islet tissue in the pancreas of the frog (confirmatory of Fischer) (6).

There is no need to refer specifically to the older work referring to changes in the islets in diabetes. The condition which was usually described was a hyaline degeneration, and the belief in this doctrine has become so widespread that it has now become orthodox to regard diabetes as a disease of the islets of Langerhans. But not a few among the pathologists in different countries have grown dissatisfied with the evidence. Thus Reitmann (26), Oertel (22) and Milne and Peters (21) have described hyaline changes in nondiabetics and even in normal animals. A recent summary of the evidence will be found in an article by Oertel (23).

EXPERIMENTS ON LIGATURE OF THE PANCREATIC DUCTS

One of the strongest supports in favor of the "separate organ" theory of the islets has been based on the effect of ligature of the pancreatic duct. It has been alleged that the operation gives rise to an atrophy of the zymogenous tubules of the pancreas, while the islets remain unchanged and no diabetes occurs. When, however, the remaining tissue consisting only of islets is extirpated diabetes ensues. The statements of different observers have, however, been very contradictory.

Milne and Peters (21) report that in the atrophy of the pancreas which follows ligature of the duct some of the islets may remain unchanged, but for the most part the islets atrophy along with the adjacent acini or else they take on appearances indistinguishable from the atrophying acini. The great majority of the structures which persist after ligature of the pancreas are really the remains of the atrophied acinous pancreatic tissue, and "collectively represent a sufficient amount of pancreas tissue to prevent diabetes."

Milne and Peters point out that perhaps the most convincing demonstration of the relative importance of the acini and islets is found in animals where the pancreas has been incompletely removed. In dogs a very minute fragment, maybe no larger than a pea, if allowed to remain, prevents diabetes. This fragment undergoes great hypertrophy. The acini become very large, and as a rule become less granular. The islets do not, however, become more numerous or larger, and in many cases no islets can be found.

But it is necessary to remind investigators that even if the islets persisted when the rest of the pancreas atropied after tying the ducts; and even if the islets were found to be more numerous after partial pancreatectomy, these facts would not prove that the islets were separate and distinct organs concerned with sugar metabolism. They would rather point to the possibility that the islets are an integral part of the pancreatic apparatus, possibly undifferentiated gland tissue, and their hypertrophy if it occurred would be an attempt to rebuild new tissue to replace that which had been removed or had atrophied.

THE ISLETS IN FISH

Rennie as we have seen (27) in 1904 gave a description of the islets of Langerhans in teleostean fishes.

Vincent and Thompson (35) examined species very different from those studied by Rennie. The last named observer investigated marine forms while Vincent and Thompson confined their attention to lake and river species. In some species it was easy to observe masses of separate islet tissue, corresponding to Rennie's "principal islet." Rennie was under the impression that in elasmobranchs the islets are wanting, though on this point he seems to have made no personal observations. As we have seen there is no difficulty in finding the islets in elasmobranchs. It was thought by Rennie that in many species the pancreas itself is free from islets; that is to say, there is a complete separation of the two kinds of tissue. In none of the species examined by Vincent and Thompson was this found to be the case. It cannot be admitted that the occurrence of patches of islet outside the limits of the pancreas carries the significance which is attached to it by Rennie and many subsequent authors. The fact that the teleostean islets are so often encapsulated loses much of its importance when it is pointed out that isolated portions of the zymogenous tissue are also frequently encapsuled.

More recent authors have been somewhat confused on the subject of the pancreas in fishes. Thus Cowdry (2) says: "It is interesting to note that in fishes the island tissue is condensed into a single large mass, quite unconnected with acinus tissue (Rennie)." Now it is only in Teleosts that such an impression might have been obtained, and even here the impression is false. Islet is always accompanied by some acinous tissue, and acinous tissue always contains some islets.

Macleod (18) has reported that no insulin could be prepared from the pancreatic tissue proper (zymogenous or acinous) of the "representative" bony fishes Lophius, Myoxocephalus, and Zoarces although a potent preparation could be obtained from the principal islets. Then he rather timidly concludes: "Although the anatomical relationships of these tissues are still somewhat obscure, the above results afford strong direct evidence for the hypothesis that insulin, as its name implies, is derived from the insular and not the zymogenous tissue of the pancreas." Now, if the principal islet really consists of nothing but islet tissue and if the pancreatic

tissue contains no islets, then it ought to have been possible to declare from Macleod's results that insulin is obtainable only from islets, but unfortunately the "islets" in Teleosts always, in my experience, contain some zymogenous tissue and the zymogenous tissue some islets. Possibly Macleod's hesitancy was due to his having studied the drawings in the paper by Vincent and Thompson where the first part of this proposition is clearly demonstrated.

But there is now a much stronger reason for doubting the value of Macleod's results upon fishes. It is doubtful how far insulin is specific even for pancreas, as it has recently been prepared from a large number of animal and vegetable tissues. The probability that such might be the case occurred to the present writer at the time that the discovery of "insulin" was announced. At my suggestion E. C. Dodds and F. Dickens (see 38) have applied their method to the submaxillary gland of the ox and have found that this organ yields 710 original Toronto rabbit units per kilo of gland. It is not easy to make any very strict comparisons as to the relative amount of potent material which may be prepared from different tissues, and this will not be possible till the chemical nature of insulin has been discovered. It is, however, clear that other glandular tissues will yield insulin in amounts comparable with that obtainable from the pancreas. It is now being suggested that insulin is manufactured in the pancreas and distributed to other tissues. Or that it is manufactured in other tissues and stored in the pancreas. Such hypotheses are of little avail in the present state of our knowledge. Nor can we state what is the relation between the fact discovered by Mering and Minkowski that extirpation of the pancreas produces diabetes, and the other fact, that a pharmacodynamically active substance capable of reducing the blood sugar in animals is widely distributed in animal and vegetable tissues.

The author's references will appear in his reprints.

Differential Diagnosis of Diseases of the Thyroid Gland

NORRIS W. GILLETTE, A.B., M.D.
Toledo, Ohio

In presenting this paper I wish especially to call attention to the few diseases and collections of symptoms that may be confounded with the diseases of the thyroid gland. Few would mistake the macroscopically large thyroid with symptoms of tachycardia, extreme irritability, tremor and exophthalmos for anything but a Graves's disease, but it must not be forgotten that diseases of the thyroid range in severity from a normal appearing gland with slight symptomatology to the exophthalmic type.

The parenchymatous goitre of adolescent girls seen in locations where goitre is endemic is in a percentage of cases a benign enlargement that disappears in early adult life, leaving as far as is possible to tell no signs of its former existence, but in these same regions a considerable fullness of the neck is so common in young female adolescents as to elicit no interest even when there begins to appear some of the definite early signs of thyrotoxicosis that come with the change from the parenchymatous type to the colloidal type. These early symptoms may be difficult of differentiating from a neurosis, inasmuch as both have some irritability as to the main symptoms with attendant excitability and tachycardia. The thyroid gland itself may be smooth, retain its shape and not be appreciably noticeable. The use of an apparatus to test the metabolism, while sometimes valuable, may often tell us but little in such cases, as a short rest in bed will quiet the individual enough so that a normal metabolism only may be noted. The Goetsch test of the injection of adrenalin is an aid, but not infallible. The best and surest aid seems to be the pulse. In a neurosis, the heart rate will vary day and night, dropping during sleep and increasing in the daytime when the individual may work herself into a state of excitement. The heart rate in diseases of the thyroid, however, does not change much, but runs along as rapidly at night as in the daytime and it demands much rest of the constitution and of the thyroid before it can be brought to normal. In those types where the etiology is definitely a deficiency of iodine ingestion the therapeutic test of giving iodine or thyroid extract may clear up the diagnosis. Small amounts of iodine, or of the extract of thyroid, called thyroxin, will reduce the size of the gland and quiet the irritability and excitability in a period of three or four weeks. Personally, I use sodium iodine in grain doses, but the iodostorine of Roche is nice to use and the thyroxin in small doses is very powerful. Dr. Englebach asserts that of all of the endocrine extracts the only one not destroyed in the stomach by its secretions is the extract of the thyroid. All others must be given hypodermically.

When the colloid of the gland begins to degenerate its smoothness and shapeliness change, for the degeneration often does not take place with any degree of equality. On one side a lump may develop that causes unsightliness or lateral pressure on the trachea or any of the other forms may appear with which we are all familiar.

Dispersed throughout the gland at this time there may develop small adenomatous areas that are noticed and felt as hard lumps. These when carefully palpated can be felt from as small as a pea in size, upward, and may or may not have developed from a diffuse adenomatosis such as has been described, but not distinguished from a parenchymatous goitre. When the gland reaches this size the absorbability of the colloid in the gland may be increased and the symptoms, if there are any, may be modified somewhat for the better by the use of iodine or thyroid extract, but the results are not perfect, and only temporary. The production of more ade-

nomatous tissue is not stopped by this medication and after a period of time that may be days, weeks or years and during which time there is always some deviation from the normal in the amount of the thyroxin thrown into the blood stream, a definite damage to the heart, kidneys and liver occurs, and often later this enlarged gland that has only been slightly harmful for a long time suddenly changes to a very definitely damaging thing that sends the pulse up anywhere from 120 to a rapidity that cannot be counted. It enlarges the heart, raises havoc with the nervous system and increases the metabolism to a point where the individual uses up his tissues far faster than he can make them. Why an almost innocuous gland should change as quickly as it often does to one capable of doing such an amount of damage has never been satisfactorily explained. The answer probably lies in some unusual burden put upon the entire system at this time, such as fatigue or an acute infection, perhaps from the tonsils and teeth, or more probably from the intestinal tract. Though cleaning up all of these sources of infection at this late date has little curative power, it should be done on general principles.

The thyrotoxic heart is an early symptom of the disease that was often considered in the past as an entity and not in relation to the thyroid, and even today a small gland moderately toxic is often overlooked as the cause of heart disturbance, and the heart treated independently of it, not as secondary to the goitre.

Coincident with a small toxic gland there may be infected tonsils or decaying teeth, which are often considered as sources of the trouble of the malfunctioning heart and indeed it is often most difficult in some cases to draw a definite line and say that the thyroid is entirely at fault when we know that infections are so commonly the cause of a bad heart. If there is some connection between an infection and the toxic thyroid then this focus would affect both the heart and the gland, with the latter superimposing its toxicity upon that caused by the infection as such. In such cases there is an irritable heart out of all proportion to what we might reasonably expect from a small focus of infection alone, or the thyroid, if but moderately toxic. There is no empirical answer to this. The thyroid if severely toxic will do much permanent damage in a short time and it is advisable not to procrastinate in these cases, but at once to eliminate the gland. In moderately toxic, or, better still in mildly toxic cases, it may be safe to delay long enough to treat the infection first.

However, where there is no definite infection and still some tachycardia with palpitation there seems little excuse for overlooking the thyroid even in the absence of a great enlargement.

It is an important, distinguishing point to note that there is seldom ever a faulty heart due to thyrotoxicosis that does not have with it other symptoms of the disease. I have not seen such a heart that did not have associated with it some irritability and hypersensitiveness.

The diagnosis of a physiological enlargement of the thyroid during pregnancy from a toxic or potentially dangerous goitre is of great interest to every accoucheur. Many women have some slight enlargement of the gland during pregnancy that disappears after parturition, not to be heard of again until the next pregnancy, or not even then, perhaps. There may be even present some signs of toxicity developing that are not troublesome or dangerous and act only as a slight added strain to the burdens of childbearing. On the other hand quite a different condition exists at times with the goitre at time of pregnancy. The disturbed imbalance of the secretions of the ductless glands manifests itself in an acute flaring up of all of the terrific symptoms of toxic goitre.

The future mother becomes alarmed, worried about herself and her child, restless and sleepless. The heart hurries, many times gastrointestinal symptoms are acute with diarrhea, and without doubt the entire system is being dealt a blow from which it can only partially recover at best. It is a fine point in diagnosis to decide at an early date whether we have a thyroid gland that is going to remain relatively quiescent during pregnancy or whether the gland will increase its activity to the danger point. Medical treatment is difficult under the most favorable circumstances. When we find the gland is becoming more toxic in early pregnancy, I believe that the gland should be removed at the earliest date to enable the mother to carry the child to term, for otherwise the child would be lost at a later date, perhaps, and the mother's health irreparably damaged. Later in pregnancy, Crotti is recommending that Cesarean section be done first. This gives the child a chance for life and does not subject the mother to the rigors of parturition. The mother is given a physiological rest, enabling her to recover enough to have the gland more safely removed at a later date. The procedure seems logical, perhaps. I have removed the gland early in pregnancy when toxic with most happy results, but have not seen such a case in which I felt justified in recommending Cesarean section. It is a peculiar fact that only very seldom does a woman suffering with Graves disease become pregnant. Peterson, who has seen many thousands of deliveries, has only two pregnancies in his vast experience occurring in the presence of the disease. The reason may be disturbed ovarian function, but to my mind the answer is to be sought in the higher metabolic rate. The cells attempting to keep a foothold inside the uterus may be poisoned by the thyrotoxicosis or it may be that the nutrition is as poor as it is for the other tissues, and the fetal cells die of starvation. This does not of course apply to enlargements of the thyroid without toxicity or goitre developing toxicity during pregnancy.

The enlargement of the neck is not pathognomonic of goitre. There are conditions that may show enlargement here or may cause pressure symptoms on the trachea in the mediastinum, as tumors of the thymus, malignancy of the mediastinum, and aneurysm of the aorta. All these may give the same choking sensations that come with intrathoracic goitre. The fluoroscope is often of great help in the diagnosis of goitre in the mediastinum both by showing the shape of the gland and by demonstrating the up and down movement of it in connection with

movements of the trachea. Only when the gland is extremely large or very adherent do we fail to get these movements on deglutition. Conditions that simulate the goitre neck are also Hodgkins's disease, cysts and cellulitis.

CONCLUSIONS

In most cases the diagnosis of goitre does not present as difficult a problem as does the differentiation of type, difficulty of prognosis, and treatment after the diagnosis has been made.

Clinical Notes on the Selective Tissue Action of the Posterior Pituitary Gland*

ROBERT C. MOEHLIG, M.D.,
Detroit, Mich.

It is reasonable to assume that in the course of evolution the individual endocrine glands have undergone an adaptive change of function from the lower to the higher forms of life as stressed by Gaskell (19). We learn that the thyroid and pituitary glands at one stage in evolution emptied their secretion directly into the upper alimentary tract suggesting that these structures were fundamentally concerned with digestion, and as we go higher in the scale this secretion is emptied directly into the blood stream, thus affecting the foodstuffs secondarily. Gaskell (19) believes that the pituitary, the principal organ of excretion in some lower forms, is homologous with the coxal gland in the Limulus (crab). Such analogies strongly suggest that there is an intimate relationship between the endocrine and other tissues based upon their morphology and embryological relationships. If we follow these closely we can construct a system of endocrine and tissue relationships which is helpful in explaining many clinical phenomena.

Evidence is accumulating that certain tissues furnish substances which nourish and activate the functions of other cell groups. Crile (11) states, "In this interrelationship of the brain, the thyroid and the suprarenals, we have what, perhaps, is the master key to automatic action of the body, that is, through the special senses environmental stimuli reach the brain and cause it to liberate energy, which in turn activates certain other organs and tissues, among which are the thyroid and suprarenals. Many writers such as Glynn (21), Falta (17a), Bulloch and Sequeira (5) have noted that hyperfunctionating hypernephromata produce precocious sexuality in the young, thus demonstrating a close relationship between the suprarenal cortex and the sex glands.

The relationship of the pituitary to body growth is a well known clinical fact tending to support the view that certain tissues furnish substances which activate the function of other cell groups, Keith (31) believing, for example, that the anterior lobe of the pituitary renders osteoblasts hypersensitive to the various stresses which fall on the human skeleton during life.

Carrel (7) says "the presence, in embryonic tissue juices and in glandular and leucocytic extracts from adult animals, of principles increasing the rate of multiplication of fibroblasts and epithelial cells suggested the possibility that these substances are secreted by leucocytes and endocrine glands—as trephones are also present in the aqueous extracts of glandular and other tissues, it is permissible to suppose that endocrine glands, like leucocytes, may secrete nutrient substances for certain tissues, and not only hormones."

In a previous communication the evidence pointing to a selective action of the suprarenal cortex secretion on mesothelial tissues was discussed (35). The conclusions reached were as follows:

1. The suprarenal cortex secretion has a selective action on mesothelial tissues.
2. The normal development and continuous normal functioning of the sexual glands and skeletal muscular system is dependent upon the normal functioning of the suprarenal cortex.
3. Anterior cerebral defects include the pituitary gland, which in turn are accompanied by suprarenal cortex defects. That the mesenchyme and mesothelium are closely related was emphasized in the previous communication. Lewis (32) concluded that the mesothelium is to be considered not as a tissue differentiated from the mesenchyme, but merely as a change or transformation in form; and Clarke's (9) experiments tend to show that mesothelium can be formed from the mesenchyme, even in adult life.

The following discussion will present the clinical evidence tending to show the selective action of the posterior pituitary lobe secretion on mesenchymal tissues. It will be noted that the suprarenal cortex, as part of mesenchyme, is involved in pituitary disease and therefore, through the intermediary of the suprarenal cortex, the mesothelial tissues are involved as well.

From the mesenchyme are derived the following tissues: 1. Connective tissue, cutis, tendons, etc., cartilage, bone—bone marrows, dentine and cementine of teeth. 2. Lymph glands—lymphatic system. 3. Spleen. 4. Blood vessels. 5. Blood. 6. Fat cells. 7. Smooth muscle (mesenchymal portion of uterus). 8. Collecting tubules of kidney—capsule of Bowman. 9. Suprarenal cortex.

The involvement of the suprarenal cortex produces changes in the mesothelial tissues as has been reported, but for the sake of clearness these are given again: 1. Peritoneum. 2. Pleura. 3. Pericardium. 4. Urogenitals: a, Wolffian body, b, kidney (non-

*From the Department of Internal Medicine, Harper Hospital, Detroit, Mich.

mesenchymal portion), c, ovary—testicle—prostate, etc, d, oviduct: A. Uterus (nonmesenchymal portion). B. Vagina. 5. Striated muscles: skeletal, cardiac.

Pituitary disease produces changes in the above named tissues, as I will attempt to show.

By posterior lobe secretion is meant the secretion obtained from the pars intermedia and the pars nervosa. All commercial preparations are prepared from both of these structures.

The clinical forms of pituitary diseases may roughly be divided into hypofunctioning and hyperfunctioning states. However, hypofunctioning may follow hyperfunctioning, such as is believed to be the case in acromegaly. It is evident that the age of onset, viz.: pre or post adolescent, has a great deal to do with the degree of changes found in these tissues; likewise, the degree of the pathological changes in the pituitary gland will influence the amount of tissue change.

I will first consider hypofunction of the pituitary gland. The tissues will be discussed in the order mentioned previously under mesenchyme. Hypofunction (Dystrophia adiposogenitalis, certain cases of obesity).

Connective tissue.—The texture of the connective tissue is delicate. The skin in the severer forms may be white and transparent like alabaster. Falta (17b) says "In dystrophia adiposogenitalis the skin shows a quite characteristic texture. It is often described as alabasterlike, is remarkably delicate and white, mostly is cool to the touch, and sometimes is dry and exfoliates readily."

Cartilage.—There is underdevelopment of the cartilage, as reported by so many authors (12). The larynx in the preadolescent variety remains small. The epiphyses fail to ossify and remain cartilaginous. Cases are reported of defects in membranous bones associated with dwarfism and diabetes insipidus (25).

Bone.—Beck (15a) says that one of the important functions of the pituitary is to stimulate connective tissue growth, especially that of bone, and involvement of the bones is a constant finding in hypofunction of the pituitary in the preadolescent stage. There is inhibition of ossification and defective skeletal development. In the later stages of the growing period, growth may suddenly become arrested and the infantile changes are permanent. In the severer forms of hypofunction, the appearance of the bone nuclei is delayed and the epiphyses remain ununited and so the long bones are underdeveloped.

Tendons.—The tendons are proportionate to the bone development and are, therefore, small.

Dentine and Cementine of Teeth.—Deciduous and permanent teeth are soft and crumbly, decay sets in very early and the dentine and cementine of the teeth are poorly developed or not all present. Ridging and hollowing are frequent.

Lymph glands.—The lymph glands are small and hypoplastic. The hypoplastic lymph glands are no doubt related to the hypoplasia of the whole hematopoietic system (bone, spleen, blood vessels, etc.)

Spleen.—The spleen is much smaller than normal, sharing in the general splanchnomicria (4-42).

Blood vessels.—Hypoplasia affecting the vascular coats is present. The aorta is small. The blood-pressure is low (16a).

Blood.—Falta (17c) says "Almost regularly in hypophysealdystrophy are found alterations of the blood picture. If we summarize all these cases, we find that there is mostly only a slight reduction of erythrocyte count or none at all (or even after operation an increase in the number of erythrocytes). While in all cases there was not an appreciable reduction of hemoglobin, the leucocyte count was often diminished, and in one case increased. Most important is the result of the differential count of the leucocytes. Almost in all cases the number of neutrophilic cells is, relatively, markedly reduced, while that of the mononuclears, and especially the lymphocytes relatively and also absolutely raised. The eosinophiles show in many cases an appreciable increase. After operation the leucocyte picture may revert to normal." Experimental evidence comes to our aid in supporting the effect of the pituitary on blood cells. Gonalous (23) has shown that the blood of young hypophysectomized dogs retained its infantile character. There was a reduced number of red corpuscles and an increased number of polymorphonuclear and eosinophilic leucocytes. It is to be expected that the younger the animal the more marked would be the infantile character of the blood. Collins and Baudot (10) conclude that the embryonic pituitary has a hematopoietic function and Watrin (44) also believes that the pituitary has an erythropoietic function, while Brown and Keith (3) from their work on obese individuals conclude in part, that the circulating blood and plasma volumes when compared to body weight are smaller in obese than in normal persons. In their series, when a marked decrease in these occurred there was evidence of anemia. The relation of pituitary to fat cells I will consider later.

Smooth muscle.—The tonus of smooth muscle in hypofunction states is very much diminished, intestinal atony being the rule and in the preadolescent variety the uterus is infantile. Englebach and Tierney (16f), from their large clinical material, emphasize the atony of the smooth muscle saying that the control of the contraction of the unstriped muscles, particularly those of the intestine and uterus as well as of the bladder, vascular and bronchial systems, is one of the most striking and easily demonstrable effects of the secretion of the posterior lobe; hence the use of the virgin guineapig uterus in assaying posterior lobe extracts.

Collecting tubules of kidney and capsule of Bowman.—In hypofunction diabetes insipidus is the rule the kidneys excreting enormous amounts of urine. There still is, however, controversy whether the posterior lobe is responsible for diabetes insipidus or whether the hypothalamic area is responsible. Lewis (15c) says that in man and several other animals the pars intermedia is most abundant around the neck of the posterior lobe and spreads over and on to the adjacent surface of the brain. One could understand from this that irritation near the hypophysis might produce this syndrome. Weir (45) concludes in part that changes in the excretion of nitrogen, chlorides, acids and ammonia may be due

to direct action of the pituitary extract on the kidney or may be secondary to the changes in water excretion although Falta (17d) concludes that irritation of the posterior lobe or irritation of a definite place in the brainstem leads to polyuria. He suggests the possibility that there may be a nervous connection between the nervous centres in the brainstem and the posterior lobe.

Biedl (2a) quotes Ide to the effect that the pituitary is an older sister of the genitourinary apparatus and Gaskell (19) believed that the pituitary was at one time an excretory organ. It is well known that the posterior lobe extracts give two apparently opposed sets of reactions. One can understand that if the renal cells have not the stimulus from the posterior lobe secretion they do not function so that water is excreted in large quantities. It may on the other hand act as a diuretic by stimulating the renal cells to activity or if the dose is large enough it may act as a stimulus which produces a greater concentration and therefore has an antidiuretic effect. The difference it would seem to me, would be in the degree of renal activity which the posterior lobe secretion produces.

Fat cells.—An interesting example of the selective action of the posterior lobe secretion on mesenchymal tissues is its effect on fat cells. In hypofunction of the pituitary, as in dystrophia adiposogenitalis, there is a large deposit of fat in the body. It is my belief that whenever we find a disturbance of fat metabolism there is a disturbance of the pituitary. Diseases of the pituitary produce changes in the suprarenal cortex with consequent alteration in the lipoids and this cortical change produces alteration in the lipoids of the sex glands. The distribution of the fat does not seem to me to be of particular consequence—it all depends upon the degree of pituitary involvement. In hypothyroidism and hypogonadism we have resulting pituitary changes and in the face of this involvement we must not ascribe the obesity to the thyroid alone or to the sex glands. Evidently the same factor (pituitary) is in control of the obesity in all cases.

Carbohydrate metabolism.—The close relationship existing between carbohydrate and fat metabolism need not be emphasized. It is common observation that hypopituitarism is accompanied by a heightened carbohydrate tolerance and that hyperpituitarism is accompanied by a lessened carbohydrate tolerance. Ainslee and I (36) have completed experiments which verify Burns' (6) experiments showing that posterior lobe extracts and insulin are antagonistic. Posterior lobe extracts cause a temporary rise in the blood sugar. It would be interesting to speculate whether this is due to the conversion of some of the lower fat products such as glyceric aldehyde into glucose.

Suprarenal cortex.—It is frequently found to be atrophic in hypofunction of the pituitary. The suprarenal cortex reflects the state of the pituitary, particularly the posterior lobe, as experimental evidence shows. Hoffstatter's (28) experiments of injecting posterior lobe extracts into seventy rabbits showed that the most constant finding was the enlargement of the suprarenals. The suprarenal cortex was hypertrophic. In the previous article (35) evidence was presented to show that brain defects involving the pituitary gland are accompanied by defects in the suprarenal cortex and Falta (17e) cites a case of dystrophia adiposogenitalis in which the atrophy affected exclusively the cortex. Ponfick (39) cites a case in which the pituitary was partially destroyed and the suprarenal cortex was small. Gougerot and Gy (17f) report a case in which the pituitary was sclerosed and the suprarenals likewise were sclerosed, but chiefly the cortex. If we accept the conclusion that the suprarenal cortex secretion has a selective action on mesothelial tissues, then pituitary involvement through the intermediary of the suprarenal cortex affects the mesothelial tissues. From a practical viewpoint the important mesothelial tissues are the sex glands and the skeletal muscular system. In hypofunction of the pituitary the well known lack of genital development is an outstanding feature. Lisser (33) showed that the prostate as well shares in the underdevelopment of the sex glands. Women are frigid, sterile and, depending on the degree of involvement, have amenorrhea. The genitalia are underdeveloped. In men the testicles remain small showing absence of spermatogenesis. Secondary sex characteristics are absent in the preadolescent cases.

The skeletal musculature in hypofunction of the pituitary is practically always involved, Goodhart and Janney (30) believing that the pituitary is concerned with muscular dystrophy. Muscular asthenia in some cases closely approaches that of Addison's disease and the histological examination of the muscle tissue reveals degenerative and atrophic changes. Infiltration with fat has also been reported (17g-34) The heart muscle likewise is atrophic.

(Acromegaly, Gigantism). In hyperfunction of the pituitary we see clinically the opposite condition to hypofunction. I wish to reemphasize that many of the symptoms and changes noted in the tissues are, of course, dependent upon the stage of the disease. I refer particularly to acromegaly, in which disease there is in the primary stage a hyperpituitarism and in the secondary stage a hypopituitarism.

Connective tissue.—The connective tissue is everywhere increased. In some cases fibrous tumors form, giving rise to Von Recklinghausen's disease and molluscum fibrosum. Castro (8), for instance, reported Von Recklinghausen's disease with acromegaly. Biedl (2f) emphasizes the swelling of the subcutaneous tissues.

Cartilage.—All cartilaginous structures increase in size. The larynx is very large with general overgrowth as noted by Chevalier Jackson (29). The voice, including that of women, becomes deep. The cartilage of the ears is also enormously enlarged.

Bone.—The bony changes are one of the most characteristic phases of the disease. The bones are unusually large and if the disease develops in postadolescence then the acromegalic type of bone formation is present, that is, the epiphyseal ossification broadens so that there is an increase in breadth more than in length. The bony attachments for the muscles are enlarged.

Dentine and cementine of teeth.—The teeth are very well developed, being enlarged and separated. Prognathism is frequent.

Lymph glands.—The lymph glands are enlarged and show a true hypertrophy. Goldstein (22) reports a case of acromegaly with lymphatic leucemia in which there was splenomegaly with lymphomegaly. Lymphatic enlargement is, however, not characteristic of acromegaly alone as many other endocrine diseases show this.

Spleen.—The enlargement of the spleen is practically a constant accompaniment of hyperpituitarism. Falta (17h) says that the splenomegaly is a partial manifestation of the enlargement of the lymphatic apparatus.

Blood vessels.—Arteriosclerosis is one of the earliest changes seen in hyperpituitarism. Klebs (15d), Brooks (15d) and others stress the blood vessel findings. The blood vessels become dilated and the microscopical examination shows that all three coats are involved. There is usually an increase in blood pressure. Head (27) reports two cases of multiple hemangiomata of the skin in association with dyspituitarism. Pribram (40) reports a case of Raynaud's disease in which was found an enlarged sella but no evidence of acromegaly. Boettiger and Oeconomaki (15d) have also observed signs of Raynaud's disease in acromegaly. Nicolis (38) found an enlarged sella in Raynaud's disease.

Blood.—In the early stages of hyperpituitarism there is noted an increase of blood volume as one would expect because of the bone marrow hyperplasia and general lymphatic enlargement. Beattie and Dickson (1) in three cases of acromegaly found an increase of the red blood cells. Chvostek (15d) states that the blood is often found at necropsy to be increased in quantity. Both polycythemia and slight anemia may occur. Relative lymphocytosis is also found (Franchini and Giglioli (18)). In the hypofunction stage of acromegaly reduction in the number of erythrocytes and polymorphonuclears are found.

Fat cells.—The relation of the posterior lobe to fat metabolism is of greatest importance. In hyperpituitarism there is an increased fat metabolism, the fat deposit being in proportion to the general bodily increase so that a good panniculus is present but obesity is absent and a marked hyperpituitarism may result in emaciation. Rabbits injected with posterior lobe extract over a course of time results in the animals being thinner than the controls. (Ainslee and Moehlig (36)). Cholesterin metabolism it seems is influenced by the pituitary secretion and that of the suprarenal cortex, the latter as noted by Goormaghtigh (24) in the case of infections pouring out cholesterin and proceeding to secrete more. Gonalous (23) showed that the pituitary and chiefly the posterior lobe contains a considerable amount of cholesterin, and in dogs an increase in circulating cholesterin results from hypophysectomy. Lack of these secretions results in lipoidemia and cholesterinemia. Likewise the reason why fat individuals are pre-disposed to cholelithiasis is evident. There is an increased stimulus to cholesterin formation from the hyperactive pituitary and suprarenal cortex. The obese individuals are, of course, predisposed to diabetes, as Joslin so well emphasized.

Mori (37) fed rabbits with fat. He found the cortex was enlarged and the amount of neutral fats and cholesterin ester was increased. Lipemia and cholesterinemia were also found in accordance with the amounts contained in the suprarenal. Hence the suprarenal seems to be an organ related to the metabolism of neutral fat and cholesterin. The changes were never found in the suprarenal medulla.

Lipoidemia is often present in severe diabetes in which the suprarenal cortex is atrophic (43). This may be due to exhaustion of the pituitary mechanism (posterior pituitary lobe and suprarenal cortex). The suprarenal cortex atrophy also accounts for the sexual hypofunction and extreme asthenia seen in the later stages of diabetes. Changes in the pituitary are frequently found in diabetes, and acromegalic diabetes is well known.

Smooth muscle.—Intestinal spasticity is frequent. (Engelbach and Tierney.) The use of posterior lobe extract for its contracting effect on the smooth muscle system is a well known clinical demonstration. Zondek (46) believes that the extract exerts a regulatory action on peristalsis.

Collecting tubules of kidney—capsule of Bowman.—The kidneys are enlarged and show on microscopic examination enormously enlarged glomeruli. Albuminuria is also found. Glaesnner (20) found that injections of posterior lobe extracts in nephritis lessens albuminuria and causes red blood cells to disappear.

Suprarenal cortex.—Hyperplasia and hypertrophy of the suprarenal cortex is found in hyperpituitarism. In the hyperactive acromegalic state, hyperplasia affecting especially the suprarenal cortex is found. Delille (13), Amsler, Ausch, Schroeder, Mullaby, Harbitz (15f), Biedl (2c), Falta (17), Elterer and many others have found hyperplastic suprarenals. Falta (17h) says it is very probable that in the future when we pay more exact attention to the relations of the pituitary and suprarenals, we will find hyperplasia of the suprarenals, and especially of the cortex, in many cases of acromegaly.

Therefore, if my opinion is correct that the suprarenal cortex secretion has a selective action on mesothelial tissues, the hyperplastic state of the suprarenal cortex should result in hyperactivity and development of the mesothelial tissues. As before mentioned, the important mesothelial tissues from a clinical viewpoint are the sex glands and skeletal musculature. Hyperplasia of the sex glands with symptomatic increase of function is present in the earlier stages of acromegaly. Hatai (26) found that in white rats "a sex difference (in the pituitary) appears in animals weighing fifty grams or more; that is to say, at precisely the same stage of development as in the case of the suprarenals." The pars intermedia and posterior lobe resemble the suprarenals and the parathyroids in possessing a high growth energy.

The interstitial glands have an increased function. All the secondary sex characteristics are sharply accentuated. Women become masculine in type and after a period of increased menstruation the latter ceases entirely. The external genitalia are hyperplastic and their dimensions increased. In the later stages the interstitial gland function lessens. Absence of spermatogenesis and oogenesis results in the later stages.

The skeletal musculature at the beginning shows an immense hypertrophy including that of the heart. Acromegalics in the early stages are very muscular and strong, and as Engelbach and Tierney (16c) state, these individuals acquire muscular strength without exercise. They are able to perform feats of great strength. The heart muscle hypertrophies so that a relative valvular insufficiency results. In the hypofunction stage extreme weakness results. Duchesneau (14) states that the muscles in this stage reveal atrophic, degenerative and sclerotic changes. Martinotti believes that the atrophic state is preceded by one of hypertrophy, as he observed an increased diameter of the muscle fibres and proliferation of the sarcolemma nuclei. Brooks also observed mitoses in these nuclei. The supposition that a preliminary stage of muscular hypertrophy exists is greatly strengthened by the fact of the characteristic bony hypertrophy at points of muscular insertion which we have described as being the most striking skeletal changes. Fibroids of the uterus are frequently present.

Mesenchymal Tissues	*Hypofunction*	*Hyperfunction*
	(*Preadolescent type of disease*)	
Connective Tissue	Not well developed	Increased
Cutis	Alabaster skin	Thickened
Tendons	Small	Large
Cartilage	Not well developed No ossification	Large well developed —ossified
Bone	Undergrowth—small	Large overgrowth
Dentine and Cementine	Soft crumbly—poorly developed	Large—well developed —far apart
Lymph Glands	Small—hypoplastic	Large—hypertrophic
Blood Vessels	Hypotonia—small aorta	Arteriosclerosis—hypertension
Blood	Diminished volume—anemia	Polycythemia—increased volume
Fat cells	Increased due to decreased fat metabolism.	Increased volume fat metabolism
Smooth muscle (uterine portion)	Atony—infantile uterus	Increased muscle tone normal or fibroid uterus.
Collecting tubules, capsule of Bowman	Diabetes Insipidus Polyuria — lessened function.	Enormously enlarged —increased function
Suprarenal Cortex	Atrophic—aplastic	Hyperplastic
Mesothelial tissues		
Sex Glands	Small—not developed	Enlarged—hyperactive
Skeletal musculature	Poorly developed — fatigue	Hypertrophied—great strength
Heart	Small	Large—hypertrophied

SUMMARY[1]

1. Clinical evidence has been presented which tends to show that the secretion of the posterior lobe of the pituitary gland has a selective action on mesenchymal tissues.
2. The suprarenal cortex as part of the mesenchyme, is involved through pituitary pathology.
3. The suprarenal cortex secretion has a selective action on the mesothelial tissues.
4. Through the intermediary of the suprarenal cortex, pituitary pathology produces changes in the mesothelial tissues as well as the mesenchymal.
5. Many clinical problems can be better understood on an embryological basis as presented in this paper.

[1]The author's references will appear in the reprints of this article.

Adrenalinuria: Its Relation to Hyperglycemia and Its Clinical Possibilities

HERMAN FRIEND, M.D.
New York

In these days of scientific advancement, an acute development of intense interest on the part of the medical profession toward the employment of the laboratory as an aid in diagnosis is unquestionably manifest. Enthusiasm is an excellent attribute but the conscientious practitioner who has had a medical career of some duration must admit that frequently laboratory reports mean nothing but lead to perplexities and disappointments in the solution of major medical problems.

It is not my intention to discuss anything that can be found in text books, but rather to call attention to some recent observations which will in some measure be of actual help to the clinician as well as to the pathologist.

Let us examine any standard textbook on physiological chemistry, and in the chapter on glycosuria we are told that traces of sugar occur in normal urine, but not in sufficient amount to be readily detected by ordinary qualitative tests. We are also informed that alkaline solutions of copper, (Fehling's and Benedict's) of bismuth (Nylander's), as well as mercury and ammoniacal silver are reduced by sugars. Finally come the polariscope, phenylhydrazine and fermentation as means of differentiation. Proceeding in more detail with the first three it is well known that Fehling's and Benedict's solutions are reduced by uric acid and creatinine, while Nylander's solution is not affected by these and is further sensitive to 0.08 per cent. glucose.

In another paper of recent publication (1), I described a method for the quantitative estimation of adrenalin in urine and casually mentioned the fact that adrenalin reduces Fehling's, Benedict's and Nylander's solutions and that it gives a red color with picric acid and sodium carbonate. The clinical significance of these reactions will be elaborated upon here and other tests common to this base and which are of diagnostic value will be introduced. Before, however, entering into this, various chemical tests for epinepherine will be given for the sake of clearness.

Adrenalin reduces Fehling's, Benedict's and Nylander's solutions identical of sugar. It reduces mercury, ammoniacal silver, and gold and platinum chloride solutions very energetically in cold. With Millon's reagent it causes a cherry red color similar to tyrosin. Ferric chloride produces an emerald green which changes to red as with tyrosin. Sulphanilic nitrous acids with ammonia produce a red color which is proportional to the adrenalin concentration (basis of author's determination). A

saturated solution of picric acid with sodium carbonate and heat (the Lewis and Benedict blood sugar method) produces the same red color typical of sugar. It obviously gives the Folin test for creatinine in blood. It also reacts with the new Folin blood sugar determination. A concentrated solution of sodium nitroprusside conducted as per the Le Nobel test for acetone in urine gives a reddish violet ring with adrenalin not identical with that of acetone, yet easily mistakable. A yellowish pink color is sometimes obtained. Epinepherine is optically active and according to most observers is levorotatory, while others have reported the synthetic product to be dextrorotatory. It has been shown by Kariya and Tamaka (2) and Menten and Crile (3) to be capable of converting venous blood into arterial blood upon exposure to air and of converting hemoglobin into oxyhemoglobin. The reader is no doubt familiar with the popular phosphotungstic acid (uric acid) test for adrenalin, Folin's assay, and the effect of all oxidizing agents upon the substance.

It will be readily seen from the foregoing that some of the slight reductions frequently observed in urine with the Fehling or Benedict test might be due to adrenalin. Differentiation tests particularly in traces have not been found to be helpful. Adrenalin determinations carried out experimentally on just such urines disclosed in a large number an excessive amount of adrenalin to be present. Normally, epinepherine has been found by me upon application of the estimation to be present in urine between 0.2—0.4 mgm. per 100 c. c. These amounts and up to about 0.5 mgm. do not cause any change with either Fehling's or Benedict's. It is of interest that in some cases of diabetes mellitus in which I found as high as four to five per cent. sugar in the urine which was identified as glucose, blood sugar high, adrenalin estimations showed in some an increase as high as 1.0 to 1.5 mgm. per 100 c. c., while others showed an absolute absence of this substance. It is common to find both albumen and casts in some diabetic urines while others have an abundance of calcium oxalate crystals. The significance of these crystals will be the subject of a subsequent paper. The albumen and casts, however, should not be simply considered a kidney involvement when it is possible that the same agent that may be causing the nephritis, may also be a contributing factor toward the diabetes. It is far remote from my mind to dispute the well established and important part played by the pancreas in carbohydrate metabolism; still, while the pancreatic theory of diabetes has by far the greater number of followers and while the fact that depancreatized dogs become diabetic has been established, the pancreas as the seat of alteration in all human diabetes has not been proved and is perhaps questionable. It is admitted by Allen in his book *Glycosuria and Diabetes* that there are many cases of human diabetes in which no anatomical alteration of the pancreas has been demonstrated, for which the existence of a functional pancreatic disturbance is admitted as the cause in these cases. Bearing this out, experiments performed by Cannon, McIver and Bliss (4) show that the sympathetic control of the discharge of adrenalin plays an essential part. Briefly, this work was carried out on cats in which the heart was isolated from the nervous system. Chloralose was used as an anesthetic. The blood sugar was reduced by injections of insulin. When the percentage fell below 0.1 to 0.07 per cent. with intact adrenal glands, there was an increase in the heart rate and a checking of the fall in sugar. Where the adrenals were removed or isolated from the nervous system these changes did not occur and the reduction of blood sugar continued until the animal died. It is commonly believed that intravenous injections of adrenalin cause hyperglycemia, glycosuria, and if continued for some time, kidney lesions. Then Herter (5) caused both hyperglycemia and glycosuria by painting the pancreas with adrenal extract. It seems then that the pancreas must be coordinated with all the other factors of this complicated problem, namely the thyroid, adrenal and pituitary (6) glands working either as compensatory or regulating members, for, according to Sajous, the endocrine glands seem to function in harmony and any discord in one might seriously affect the others. It is admitted today that in such conditions as fevers, pneumonia and other acute infections the adrenals are involved. Concurrent with the fever and high blood pressure there is a decided reduction with the sugar reagents. In several of such cases in which the adrenalin estimation was performed the content was found to be very high, showing beyond question that the reduction was not due to sugar. It is coincidental that the kidneys are temporarily affected as shown by the albumen and casts; in fact, the blood chemistry shows a typical picture of nephritis. Acetone and diacetic acid reactions are usually strongly positive.

I have frequently noted peculiarities with the sodium nitroprusside test for acetone and have often questioned the specificity of this reaction. The ferric chloride test for diacetic acid has also given results which were strongly suggestive of being due to another substance or substances. Legal in 1882 found that sodium nitroprusside reacted with creatinine. Phenols have been reported by numerous recent observers to give a yellow color with this compound. A very recent article by Bigwood and Ladd (7), regarding positive acetone and diacetic acid reactions in diabetic and nephritic cases void of clinical symptoms, concluded as follows:

1. A solution of pure acetone gives a color reaction with sodium nitroprusside.

2. A solution of diacetic acid as free as possible from acetone also gives a color reaction with sodium nitroprusside.

3. Such a solution of diacetic acid gives a color reaction which ferric chloride acetone does not.

4. Electrolytes present in urine, especially sodium chloride, tend to intensify the color of the ring in the sodium nitroprusside test.

5. Quantitatively because of the many interfering substances the tests as routinely done serve as only the crudest approximations in indicating the amounts of acetone and diacetic acid present. The ferric chloride test appears to give results somewhat less eccentric than the nitroprusside test.

I am in accord with these findings and can add as already mentioned that pure crystals of adrenalin both in test tube and added to urine give a reddish violet color with sodium nitroprusside; with some urines it has been my experience to obtain at times a yellowish pink which has as yet no explanation. Hubbard and Wright (8), in studying the effect of adrenalin on blood constituents, also found that acetone bodies appear after the injections of small amounts of adrenalin chloride. This suggests a connection between the acetone reaction and the Benedict reduction in pneumonia and allied conditions.

In regard to blood chemistry, accurate data on the chemical composition of blood are of comparatively recent origin. Although the chemical study of blood has yielded a very broad scope in the diagnosis and treatment of disease yet the last word on the subject is still a good way off. Of primary importance again from the standpoint of adrenalin is the interpretation of sugar content of blood. Dobson, in 1775, was the first to recognize a sugar like substance in blood, but it was actually discovered by Claude Bernard some seventy years later, who made many of our classic observations on carbohydrate metabolism and first noted the connection between hyperglycemia and glycosuria. It remained, however, for Bang (9) and Lewis and Benedict (10) in 1913 to introduce methods for its estimation in blood. The former method being a gravimetric-volumetric one precluded extensive clinical application, which led to the survival of the Lewis and Benedict method. This last has only recently been replaced by the Folin method.

The subject of diabetes is entirely too vast and out of place in this paper, but the socalled renal diabetes will be briefly considered. Lépine in 1895 postulated the existence of a rather interesting condition in which the glycosuria is actually the result of renal disease and not due to hyperglycemia as in diabetes. The literature records a large number of these cases in which there is definite evidence of renal disease aside from the glycosuria, but a large number would appear to be entirely free from the symptoms associated with kidney disease. These present a history of low grade glycosuria without the classic symptoms of diabetes mellitus and are diagnosed as the socalled "renal diabetes." They are accompanied by a hypoglycemia. Adrenalin estimations done on a large number of such cases showed an excessive amount of adrenalin to be present in the urine from which it might be inferred that the reduction is due to adrenalin and not glucose.

In severe nephritis Meyers & Killian (11), De Niord and Schreiner (12), Williams and Humphreys (13) have shown the blood sugar to be high: in fact, the consensus of opinion is that the blood sugar varies directly with the severity of the disease. It has been reported by Baily (14) and is of importance that in marked interference with kidney function very small amounts or no sugar appears in the urine, whereas the blood sugar is very high, in fact, as high as 0.2 to 0.3 per cent. blood sugars have been observed before traces of sugar appear in the urine. This condition of hyperglycemia has as yet not been satisfactorily answered except that some disturbance of the adrenals or other glands has been suspected for both the high blood sugar and pressure. It is generally conceded that creatinine interference in blood sugar estimations with the Lewis and Benedict method is a basis of error. While there is no doubt that creatinine does influence some blood sugar findings, it is much less than implied and does not invalidate any deductions based on this finding; moreover, as already mentioned, adrenalin reacts with all the blood sugar estimations causing by far a much greater error; in fact I have definite evidence[1] that we are actually estimating adrenalin and not sugar. Aside from my own experiments just referred to, Winter and Smith (15) have observed that the mixture of sugars present after the injection of adrenalin appears to be similar to that existing in diabetic blood before the injection of insulin. Phenyl osazones have been prepared from the blood of rabbits after the adrenalin, and from the blood of diabetics; crystalline osazones other than glucozone have been observed. Slight retentions of creatinine have also been found to occur in syphilis, certain heart conditions, sometimes in fevers, in pneumonia and in some cases of advanced diabetes. These have no explanation. Since picric acid is also employed as the basis of this test, it should not be surprising that adrenalin reacts with the Folin creatinine estimation in blood. To prove this with certainty, I ran some pure crystals of adrenalin P. D., through the Folin blood creatinine test and obtained a decided deepening in color proportional to the number of crystals used. Repetition confirmed these results. This work was not quantitative but approximate.

It will now be seen that the same endocrine product may be responsible for the high blood sugar and pressure as well as influencing the creatinine. Addis, Barnett and Shevsky (16) have reported that appropriate doses of adrenalin increase the excretion of urea. The apparent acidosis or diminished carbon-dioxide content of blood in pneumonia and nephritis may be explained in perhaps two ways: first, it may result from decreased elimination of normally formed substances such as in nephritis or secondly, Tompkins, Strugis and Wearn (17) have found that epinepherine injection causes an increase in metabolic rate and influences the output of carbon-dioxide.

Let us view glycosuria from another angle. We know that in the blood we have a fluid which is composed of a great many products of intermediary metabolism, the concentration of which is kept remarkably constant. The kidneys exert a remarkable selective power for their secretions so that the various substances are maintained at definite levels of concentration in the blood. Take for example the excretion of chlorides; if a person is on an absolutely salt free diet the chlorides in the blood will remain at a constant level and the kidneys will refuse to excrete any of it. If, on the other hand, a person ingests a large amount of chlorides, the moment absorption begins and its concentration in the blood tends to rise, the kidneys at once begin to excrete chlorides so as to have a definite constant in the blood. The same is true of sugar; the promptness

[1]Unpublished experimental work almost completed.

with which the kidneys adjust themselves in regulating glucose is marvelous. The blood normally contains from 0.09 to 0.12 per cent. sugar. None of it is excreted by the kidney except as claimed by Benedict, traces of no practical importance. If, however, for some reason or other the glucose constant reaches about 150 or 180 mgm., the kidneys immediately begin to excrete it so as to lower its concentration in the blood. The idea therefore that the blood sugar should rise to as high as 0.2 to 0.3 per cent. before traces of sugar appear in the urine, or that urine should show a glycosuria without a hyperglycemia does not seem to be at all consistent. Since adrenalin is known to cause a rise in blood pressure and since it has been shown to give both the urine and blood sugar tests it is reasonable to suppose that a good many of these socalled hyperglycemias and glycosurias are actually adrenalin. It has been observed and is accepted that high blood sugar readings are obtained in hyperthyroidism (not always on a fasting stomach), while in Addison's disease the blood sugar is usually below normal. In regard to the former, experiments conducted on thyroid have not been entirely satisfactory due to great variations existing in the different commercial products. I am, however, led to believe that thyroid also gives the blood sugar tests, namely, the Lewis and Benedict. Insulin (Iletin Lilly) and pituitary extract (anterior lobe) do not react with either the urine or blood sugar tests.

Another condition which has as yet no satisfactory explanation and which appears to have its origin in the adrenals is hypertension in its relation to cardiorenal diseases. While opinion as to its cause is divided the majority attribute it to over activity of the suprarenal glands. From the laboratory viewpoint the literature is not as copious as it might be. Meyers (*Practical Analysis of Blood*) makes mention of some six complicated cases, nephritis, etc., in which the urea, sodium chloride and creatinine appear to be normal whereas the uric acid and blood sugar are high, the latter varying from 120 to 160 mgm. per 100 c. c. O'Hare (18) reports the glucose tolerance test performed on some twenty-five cases of chronic vascular hypertension in which according to his paper the element of general retention which complicates in true nephritis was not present. His results showed in the majority of cases a marked hyperglycemia varying from 130.0 to 300.0 mgm. per 100 c. c. Of these, many showed a varying glycosuria in some as high as from two to four per cent. Repetition of two bad cases done at other times showed quite a normal blood sugar with but a slight glycosuria. My own observations on a few cases, some of which were uncomplicated, showed a retention of sodium chloride and calcium with a marked hyperglycemia, without glycosuria. Remarks further than what has been generally said regarding adrenalin giving all the sugar tests, from the sparse number of cases would be a matter of conjecture. It has been shown that injections of adrenalin cause both hypertension and arteriosclerosis. Experimentally, perhaps the best known work is that of Klotz (19) who used adrenalin. It seems that adrenalin produces lesions comparable to some types of human arteriosclerosis. There is doubt whether this result is due to the blood pressure raising effect. When the hypertension effect of adrenalin is prevented by the administration of vasodilators along with it, the same arterial lesions are produced. So it appears that it might be due to some toxic effect of adrenalin rather than the mechanical effect of hypertension. It is therefore obvious that adrenalin might be one of the natural causes and again the substance that we are calling sugar may be epinepherine.

The foregoing are perhaps only a small number of conditions in which the adrenals seem to take an active part either directly or indirectly, as shown by proper interpretation of blood and urine findings. Appended are a few cases taken from some 300 unselected ones from a hospital clinic. The diagnoses were not made by the writer but were taken from the records.

Although mention has been made of a test for adrenalin in blood and correction of our blood sugar methods to distinguish between true hyperglycemia and high readings not due to glucose, I shall refrain from discussing these at this writing.

In passing, it might be well to add that it is admitted that the results of the various methods in blood chemistry are of the utmost importance. The procedure has been worked out carefully, and it takes skilled chemists to carry out these estimations accurately so that they will be of value, as apparently conflicting results are obtained when entrusted to uninstructed persons who know nothing more than motions. This is also true of urine examination for the physician must rely upon the experience and good judgment of the chemist to know when he has a clean cut reaction or when a reaction is not specific suggesting the possibility of interference with or, perhaps the reaction of a substance other than the one tested for.

CONCLUSION[1]

On the basis alone of facts presented we must differentiate between glycosuria and adrenalinuria.

We are led to suspect a relationship between high blood pressure and hyperglycemia or hyperadrenalinia in some conditions. What this relationship is should be a matter of investigation for it is certainly a new field for clinical and laboratory work. Other tests mentioned must be properly interpreted to be of any value.

A Clinical Study of Endocrine Disturbances in Rhinological and Laryngological Cases*

LOUIS HUBERT, M.D.
New York

During the last six years, in Dr. McCullagh's clinic at the Manhattan Eye, Ear and Throat Hospital, I have made quite a few observations on the possible rôle some of the glands of the internal secretions may play in the causation of certain symptoms of the nose and throat. In the short space at my disposal I shall consider briefly only such endocrine cases as I have seen and studied in the clinic, and for the purpose of elucidation I shall classify them according to the most prominent symptoms they presented. Before discussing the various cases I will first group the symptoms under the following headings:

I. Local Symptoms. 1. Rhinological: a. rhinorrhea, b. sneezing. 2. Laryngological: a. choking sensation, b. hoarseness, c. irritation of pharynx (pharyngeal neuroses.) 3. Respiratory: a. nasal obstruction. b. dyspnea, c. attacks of suffocation.

II. General Symptoms and Signs: nervousness, weakness, palpitation of the heart, mental excitability or mental dullness, headache, constipation or diarrhea; dry and pasty or moist and flushed skin, fine tremor of the tongue and outstretched fingers, rapid or slow pulse, enlarged thyroid gland, certain eye symptoms, like exophthalmos, dilatation of the pupils, etc., small sella turcica with erosion of the clinoid processes, enlarged thymus, certain abnormalities of the teeth, certain changes in the distribution of the hair, etc.

The symptoms referable to the nose and throat were the dominant symptoms for which the patients came to the clinic. The general symptoms and signs were elicited on close questioning and careful examination, and helped to determine the underlying condition, i. e., what particular endocrine gland or glands were probably involved.

1. CASES WITH RHINOLOGICAL SYMPTOMS

Rhinorrhea and Sneezing—A detailed description of the mechanism and treatment of rhinorrhea and sneezing with an analysis of thirty-four cases was the subject of a thesis before the American Laryngological, Rhinological and Otological Society. I do not consider every case of watery discharge from the nose as being of endocrine origin. However, a considerable number of patients, complaining of rhinorrhea and sneezing, are seen in whom close examination excludes intranasal causes, as well as other etiological factors, such as sensitization and intestinal disturbances, who improve or get well on endocrine therapy. Furthermore, some of these patients present certain endocrine markings, which have been described by competent observers as indicative of a mild hyperthyroidism or hypothyroidism. Other patients apparently show no obvious disturbance of the glands of internal secretions and yet they also respond to endocrine treatment. I have therefore divided these patients into three groups: 1. the mild hypothyroid, 2. the mild hyperthyroid, and 3. the indeterminate group.

Patients with moist, flushed skin, more or less rapid pulse, palpitation of the heart, nervousness and mental excitability are tentatively classed under the hyperthyroid group. Those with dry, pasty skin, more or less slow pulse, and mental dullness are tentatively classed under the hypothyroid group. A certain number, as indicated above, cannot be classified. The patients that improve markedly on thyroid extract are then considered hypothyroid, and those that improve on quinine hydrobromate, hyperthyroid types. A number of the unclassified type respond to either thyroid extract or quinine hydrobromate or to neither[1].

Patients classified as hypothyroid are given thyroid extract, one tenth grain t. i. d. The rationale of this treatment is shown by the fact that these patients are relieved not only of their rhinorrhea and sneezing but also of other symptoms of hypothyroidism, as constipation and mental dullness. For the hyperthyroid patients quinine hydrobromate, three grains in capsules, b. i. d. or t. i. d., is prescribed. These patients, too, show improvement not only in the rhinorrhea and sneezing, but also in other symptoms of hyperthyroidism, as nervousness and tachycardia.

In the indeterminate group, where it is impossible to say whether we are dealing with a mild hypothyroidism or hyperthyroidism, thyroid extract one tenth grain t. i. d. is tried for about a week. If there is improvement the drug is continued. If no improvement is evident, quinine hydrobromate is given. Some patients, however, can not tolerate the latter drug well, as it may cause dizziness, weakness and other annoying symptoms, and therefore should not be given more than one grain of the quinine hydrobromate two or three times a day.

2. CASES WITH VAGUE LARYNGOLOGICAL SYMPTOMS

Choking sensation.—In a previous article (1) attention was called to the fact that patients came to the clinic complaining of catarrh or some vague throat condition, in whom close study revealed increased stimulation of the thyroid gland. Most of these patients characterized their discomfort in the throat as a choking sensation. On questioning it was discovered that they were of a nervous temperament and had palpitation of the heart on slight exertion. They usually had a moist, flushed skin, and a fine tremor of the tongue and outstretched fingers. The thyroid gland was slightly enlarged and the pupils were usually dilated. The most characteristic and constant symptom was an increased pulse rate even at rest. These patients were sensitive to adrenaline. This should be remembered when performing an

*Read before the Section of Rhinology and Laryngology, New York Academy of Medicine, April 23, 1924.

[1]The basal metabolism is not determined, as I do not believe it would be of any practical value in these mild, borderline cases.

operation on them under local anesthesia, as most of them have diseased tonsils. Foci of infection in other parts of the body are also frequently present.

The treatment of these patients consists in the localization and elimination of all foci of infection by surgical or medical means, and the administration of quinine hydrobromate. Those patients who can not tolerate the latter drug are given adrenal residue, ten drops three times a day[1]. Of course, hygienic and dietetic treatment must not be omitted. This treatment has been successful in the clinic even in well marked cases of thyroid disease, and no operation on the thyroid gland has been performed during the last six years, except in thyroid cysts and adenomata.

Hoarseness.—Marked hoarseness caused by large goitres pressing on the laryngeal nerves with resulting paralyses of the vocal cords is not included. I wish to direct attention to patients, seen occasionally, with very slight enlargement of the thyroid gland, and with mild symptoms of hyperthyroidism, in whom the vocal cords move properly, but do not come in direct contact on phonation. These patients are only slightly hoarse. Whatever the cause of the hoarseness, it is interesting to note that it is relieved by treating the mild hyperthyroidism and not by treating the larynx. I have reported such a case (1).

Pharyngeal neuroses.—Bizzare complaints in the throat by neurotic women at the menopause are quite frequent. For the purpose of illustration the following case report is submitted.

Case I.—T. L., a widow, fifty years old, a cook by occupation, came to the Hospital, May 13, 1922, complaining of a scratching feeling in the throat and a constant desire to swallow for the last twelve months. Her previous history was of no significance, except that she had a goitre, which was first noticed when she was thirty years old. She thought the goitre developed after continued worry and excitement. She was unhappily married, at the age of seventeen, her husband having been a confirmed drunkard. When she was forty years old, the goitre had increased in size, and she suffered from palpitation of the heart and extreme nervousness. A thyroidectomy was then performed. Two years before she came to the clinic she had had her last menstruation, which up to that time was more or less regular and of normal character.

Examination of the nose and throat was practically negative. The usual local treatment to the pharynx was of no benefit to her. In view of the fact that a thyroidectomy had been performed, it was thought that perhaps too much glandular tissue had been removed, so small doses of thyroid extract were prescribed. The symptoms in the throat were not relieved, but the pulse rate was increased, and she complained of excessive nervousness and also palpitation of the heart. Thyroid extract was manifestly contraindicated. Therefore, on September 15, 1922, ovarian extract, five grains t. i. d., was substituted. Since that time she has been absolutely free from the throat symptoms, provided she did not lapse in the taking of ovarian extract. It not only relieved her of her symptoms in the throat, but also of a peculiar tingling and drawing feeling of the entire skin. As a matter of fact, she felt much better while taking the ovarian extract.

This case shows the importance of giving only one glandular product at a time. This method is not only more scientific, but safer. If, for instance, she had been given a combination of thyroid and ovarian extract, as is usually done, and it had been continued for such a long time, in order to get the effect of the ovarian extract, she certainly would have suffered from the toxic effect of the thyroid extract.

Respiratory Symptoms

Nasal obstruction.—In a previous paper (2) there are described two groups of cases belonging to the status thymicolymphaticus type. In the one group there is nasal obstruction present. Such patients are frequently referred for the removal of tonsils and adenoids. On further examination it is found that these patients, in spite of their healthful appearance, are very weak and present certain signs that have been associated with a status hypoplasticus. The thymus gland may be slightly or not enlarged.

Dyspnea and attacks of suffocation.—In the second group of cases the thymus gland is enlarged, and the most prominent symptoms are dyspnea or attacks of suffocation, especially at night. If a mother tells us that her child cannot breathe normally and has choking spells at night, it is our duty to ascertain the exact nature of the respiratory difficulty. Enlarged tonsils and adenoids do not cause dyspnea or attacks of suffocation.

Pituitary headache.—The headache, in the majority of cases we see, is due to nasal sinusitis. A definite type of pain, supposedly due to an increase of the pituitary gland in an enclosed and small sella turcica, has been described by neurologists. This pain is usually bitemporal or deep in the forehead behind the eyes. It is relieved by the administration of pituitary extract. Laryngologists see such cases very seldom. I have reported such a case (3).

Comment

Although we know little of the conditions within the body that control the endocrine glands, the importance of studying the patients from the endocrine aspect cannot be too much emphasized. If it does nothing else, it leads us to closer observations, and makes us better physicians. It forces us to consider the patient as a whole, and not only his upper respiratory tract. It makes us realize that many rhinological and laryngological phenomena can only be explained on the assumption that they are local manifestations of some general condition. Even though there is in all probability a close interrelation between the various glands of the internal secretions, it is not so easy to prove it to the satisfaction of scientific investigators. In the present state of our knowledge it is therefore wiser to use uniglandular therapy in treating supposed endocrine conditions.

In conclusion I wish to express my sincere thanks to Dr. Samuel McCullagh and to Dr. Francis White, who have given me every opportunity to study these cases.

[1]Adrenal residue is to be distinguished from adrenalin. Whereas adrenalin is derived entirely from the medulla, adrenal residue is derived mostly from the cortex of the adrenal glands.

Case II and references will appear in the author's reprints.

Bradycardia

B. T. PARSONS-SMITH, M.D., M.R.C.P.

London

Physician to Outpatients, the National Hospital for Diseases of the Heart, London

Bradycardia, as the term clearly indicates, may be taken to denote abnormal slowness of the heart beat, i. e., a rate relatively below the usually accepted standard. With reasonable allowances for functional deviations it is customary to assume the normal resting rate of the adult man to be 72 a minute, and, in a purely arbitrary fashion, we may denote and apply the term bradycardia to heart rates of 60 and under.

The sign as such is noteworthy for two reasons: 1, the rarity of the condition, and 2, the clinical phenomena which frequently coexist, incidentally also the varied etiology which, during recent years, has become increasingly simplified by the comparative study of clinical and laboratory data. The practical outcome of these latter enables us to formulate, with some precision, a fundamental basis from which to approach the problems connected with the study of bradycardia.

In conformity with the approved grades of elasticity which stamp the functional activities of all vital processes there need be no hesitation in allowing an ample latitude for the rate of the normal heart beat, hence we must recognize that a slow heart rate *per se* need not of necessity be indicative of pathological processes. Fortunately much of the haze which, until recently surrounded and fogged our conception of the heart's contraction, has now been lifted, and clearly defined details have emerged; we recognize certain specialized areas, remnants of the primitive cardiac tube, whose peculiar function it is to incept stimuli in rhythmic series, and so to assure regularity in the sequence of heart's contractions. Investigation, moreover, teaches us that the rate of discharge of stimuli from the specialized tissues differs not only according to the position of the active region, but also in virtue of influences transmitted through nervous channels, it would be natural to assume that the rate of the heart's contraction will be subservient to the focus whose effective stimulus formation proceeds at the highest rate, and that all areas less actively endowed would, under these circumstances, be submerged.

Such considerations enable us to appreciate some of the fundamental principles which underlie and regulate the speed of the heart's contraction, and it is perhaps unnecessary, in this context, to do more than mention the existence of concrete evidence which proves that the normal beat takes origin in a node of specialized tissue situated at the junction of the superior vena cava with the right auricular chamber, whose rate of discharge in the healthy resting adult is 70 to 80 a minute.

Furthermore, we recognize that the sensitivity and capacity for adaptation, which the normal heart possesses, depends upon a close interaction between the area of stimulus formation and the central nervous system; in other words, the intimate bond of association between nerve and muscle tissue; hence we may with some confidence, approach the subject of disturbed heart rhythm, and incidentally the one at present under consideration, from two separate aspects, 1, the neurogenic, and 2, the myogenic.

NEUROGENIC BRADYCARDIA

We are fully aware that, under ordinary circumstances, the heart rate is maintained in a condition of permanent check by the active intervention of the inhibitory mechanism. The tonic influence of the latter, in balanced conjunction with the opposed sympathetic impulses, has, however, an extensive range of function which renders possible the heart's adjustment to alterations in the physical environment; thus we can account for the rate alterations observable during rest, exertion, emotion, anxiety, fright, etc.; and incidentally we have direct evidence, by reason of the slowing which normally accompanies the expiratory period, of a definitely phasic variability in the tone of the inhibitory mechanism.

The foregoing remarks, though brief, not only enable us to infer that the check imposed upon the heart by the central nervous connections is inconstant in degree, but also suggest that circumstances may arise under which inhibitory effects become so far exalted as to determine slowing of rate to the level of true bradycardia.

From time to time we meet with cases in which bradycardia is a seemingly normal event, and unassociated with any symptoms of physical incapacity

or deficient exercise tolerance. Such patients may display signs of autonomic overaction in varying degree, contracted pupils, asthmatical tendencies, constipation, a cool dry skin, etc., more especially noteworthy, however, in the present context, is the existence of an augmented innervation by the cardiac vagus. In striking contrast, moreover, with certain types of myocardial degeneration to be referred to later, it is characteristic of the socalled normal bradycardia that the slow rate of beat is merely a phenomenon of the resting stage. Ample acceleration comes about to allow of the necessary adjustments during effort, and full release can be procured in the usual fashion by trial doses of atropine sulphate.

It would seem, in other words, that certain persons, notably tall healthy males, will exhibit sure evidence of hypertonus of the cardiac vagus and some authorities, notably Savill, have remarked on the possible hereditary influences which may or may not be operative in such cases. As a result, in great measure of experimental investigations, we know that slowing of the heart beat under vagal stimulation is brought about by a process of focal inhibition whose seat may be the sinoauricular node or the functional tissues connecting the upper and lower chambers.

We are familiar clinically with examples of bradycardia conforming to these types. Sinus bradycardia will present no difficulties, the slow beating of the heart will be the only abnormal physical sign; the electrocardiogram, except for the wide spacing, will be normal as regards the shape and relative sequence of the waves composing the individual complexes; the jugular curve is physiological; subjective symptoms do not exist. That the conception of vagal bradycardia may involve more than a simple slowing of the sinus rate can be proved conclusively by careful study of polygraphic or electrocardiographic curves. In the latter we recognize changes indicative of interference with the normal and coordinate passage of the heart's contractile impulse; some degree of blockage is evinced either in the vicinity of the sinus node itself or in the junctional tissues which connect the upper and lower chambers.

The term sinoauricular block, introduced by Wenckebach, is in itself sufficiently explanatory to need but a minimum of definition; the block, as such, is situated in the higher reaches of the auricular wall so that the sinus impulse fails to extend to the adjoining muscle, consequently a complete intermission of the auricular beat is brought about, and the ventricle, deprived of its normal stimulus from the upper chambers, is likewise silent. For the clinical diagnosis of sinoauricular block some form of instrumental record is essential. The curves are remarkable in that they reveal a disturbance of rhythm which, by analysis, is found to indicate intermission of whole heart cycles; the length of the pause which announces the dropped beat is peculiar in that, as a rule, it is approximately equivalent to that of two normal cycles; in point of fact it is usually just short of this measurement. In addition slight variations in the basal rhythm have been observed (1), the intermission being preceded by some degree of acceleration and followd by a temporary slowing of rate.

A large variety of causes are mentioned in connection with this somewhat rare type of cardiac irregularity; we are familiar with its appearance in the convalescent stages following certain of the acute specific fevers, also as a sequel to digitalis medication, and tobacco poisoning; quite frequently, however, we observe sinoauricular block in patients who present no ascertainable or definite reason for the advent of the disturbance. Fig. 1 is the electrocardiographic curve taken from a patient in whom irregularity of heart action was confined solely to the quickening rate following exertion; the complexes are seen to be normal in conformity and wave sequence, the intermissions were complete, their duration being rather less than that of two of the regular heart cycles; atropine brought about complete vagal release in this patient, also all tendency to the appearance of the irregularity.

Apart, however, from isolated dropped beats, and simple groupings as in the case above mentioned, sinoauricular block occasions a further and rather more striking irregularity in that it determines abrupt changes of heart rate somewhat peculiar in arrangement; these changes will be apparent during the transition stages from the quiet resting rate to the more rapid rhythm, and *vice versa,* a sudden doubling and halving of rate during these processes indicating the functional removal and return of the block at the sinus region. That such is the state of affairs may be surmised by physical examination and pulse counts during the phases between rest and effort, and confirmed in conclusive fashion by graphic registration. Such, in brief, is the usually accepted description of sinoauricular block, but there remains for mention one other specific manifestation of augmented vagal tone, viz., auriculoventricular block. The following case may be mentioned in illustration:

Case.—S. S., aged forty-seven years; seen in consultation by reason of bradycardia; past history included the usual childish ailments. Subjective symptoms nil, physical capacity excellent, active at business and unduly energetic from the athletic point of view; the normal pulse rate was 60, likewise the ventricular. Fig. 2 is a curve obtained from this patient, and portrays clearly the slow sinus rhythm also the delay in the passage from the upper to the lower chambers; the P. R. interval is prolonged, varies somewhat from beat to beat, averaging 0.25 seconds in length; normal acceleration of heart rate was brought about in this patient by effort tests, but the slow rate was resumed with undue rapidity; an injection of atropine produced a rate of 100 in twenty minutes and the electrocardiogram taken at this time showed that the P. R. interval had been diminished to 0.16 seconds.

Such then are some of the effects of vagal augmentation in conditions of health, and our next inquiry relates to a similar happening from causes of a pathological character. These may be conveniently discussed under three main headings: direct, reflex and central.

The direct embraces a somewhat varied group of disturbances which owe their being to a successive stimulation of the cardiac vagus in its course from the medulla. They may be produced by the irritation of new growths and tissue changes in the vicinity of the vagus nerve, or as a result of an actual neuritis. One might mention a large number of morbid states in association with this latter condition, but the better

known will suffice for the present context, and we may instance, under this heading, of vagal neuritis, concrete examples of the lesion as such is produced in poisoning by lead, alcohol, the toxin of diphtheria, etc., and, in addition, those varieties of the disorder which depend upon the spread of inflammatory mischief from mediastinal structures neighboring on the course of the vagus nerve.

Of bradycardia reflexly vagal in origin, we need make but brief comment; that such may occur would seem almost beyond doubt, for evidence from the clinical point of view is at times convincing. We are familiar with the bradycardia sometimes to be noted in gastrointestinal disorders, dyspepsia, gastric ulcer, and new growth, to mention only some of the affections which may set up irritation of vagal nerve endings; probably also the infrequency which occurs in emphysema and certain other pulmonary lesions is due in some measure to reflex irritation from the lungs, hence may find place in the present category. We may, however, note in passing that the whole group of reflex bradycardias is of little significance, except from the experimental point of view, and further that this type of slowing bears little if any prognostic import, the vagotonia is not permanent and the blood pressure readings are unaffected.

The remaining group deals with those varieties of vagus augmentation which are secondary to influences acting centrally on the inhibitory area in the medulla.

A disturbance in the innervation of this latter may be brought about by poisons circulating in the blood stream, and here we may refer to the central slowing brought about by digitalis medication, jaundice, and uremia, also the toxins of typhoid, diphtheria and pneumonia. The bradycardia of jaundice, doubted by certain observers, is none the less definite, and may be ascribed to the agency of the biliary acids. In simple cases these will bring about their characteristic effect via the inhibitory mechanism, and atropine will determine a full release, but the possible effect of these acids directly upon the myocardium should at all times be considered, for the presence of a toxic myocarditis will undoubtedly add to the gravity of the illness and in some measure adversely affect the prognosis. An injection of atropine will settle the question beyond doubt.

The average pulse rates of twenty patients warded for jaundice was 68, and among the records one finds frequent counts between 50 and 60.

The late stages of chronic renal disease, and, more particularly, uremia itself, are characterized by bradycardia with some regularity. The causation is by no means simple; at least two factors would seem to offer an explanation of the increased inhibition viz., the toxins circulating in the blood stream, and the increased blood pressure usually obtaining in these cases, which serves to remind us of Marey's law that, with a normally active inhibitory mechanism, the rate of the heart beat is in inverse ratio to the arterial pressure.

Our reference to vagal bradycardia central in origin may close with a note upon its occurrence in association with cerebral disease; and, for this purpose, one has drawn freely upon the records of hospital cases.

We are led to assume that a slowly increasing intracranial pressure at first causes a slow heart beat. If sudden in onset or extreme in degree the pulse may be rapid, thus we find that a large hemorrhage causes a rapid pulse, a tumor causes slowing in the early stages, but tachycardia at the end.

Interference with the cerebral circulation, as may occur from causes such as endarteritis, thrombosis, or embolism, may be sufficient to cause bradycardia, and irritation of the base of the brain, as in meningitis, is responsible, in the early stages of the disorder, for a similar result.

MYOGENIC BRADYCARDIA

A brief explanatory note may, with advantage, prelude discussion of this group of socalled myogenic bradycardia, and incidentally define its limits.

We are forced to recognize the very intimate association between nerve and muscle tissue which exists in cardiac structures at all times, and, in theory, it is impossible to divorce the one from the other, but, from the practical point of view, a broad separation would seem to be helpful, hence the existence of the present group, and the neurogenic which precedes it.

Certain types of bradycardia appear to overlap both neurogenic and myogenic groups; such for instance as that observed in convalescence from acute disease, in athletes, pregnancy, and other conditions. In the present context, however, we shall refer more especially to the condition as it arises in association with pathological states affecting the myocardial structure, in other words, those varieties of intrinsic heart disease in which slow beating is a prominent feature.

The first type of the disturbance which claims our notice is heart block, a somewhat descriptive term indicating the presence of an obstructive interference with the passage of the contractile impulse from the upper to the lower chambers; in varying degree the auricle and ventricle become dissociated, and this to the obvious disadvantage of the latter and the arterial system generally.

Our earliest authentic records of clinical heart block were made approximately a century ago. In 1827 Adams (2) published in full detail the notes of a case—a male aged sixty-eight who was subject to oppression of breathing and obstinate cough; the pulse was slow, thirty a minute; recurring attacks, apoplectiform in type, were frequent (of these there were twenty in seven years) and the heart rate at these times became slower than usual. Death followed one of the attacks; the heart was found to be fatty; there was no mention of the coronary arteries.

In 1846 Stokes (3) recorded a similar type of case. In his patient the pulse rate was 28, epileptiform seizures were frequent, usually lasting four to five minutes; fifty such attacks were noted during the last three years of this patient, and finally he succumbed in a paroxysm of unusual length.

Numerous reports of similar cases followed, and the pioneer observations of Adams and Stokes were amply confirmed. The dissociated action of the auricle and ventricle was explained as being the outcome of widespread degenerative processes in the myocardium, in fact as late as the early part of the present century the actual pathology of heart block

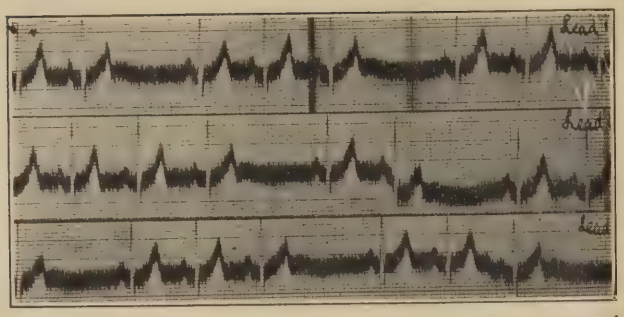

Fig. 1.—Sinoauricular block; the complexes are normally composed in each lead; frequent intermissions occur, the pauses approximating in length that of two normal beats; the intermissions are complete, involving both upper and lower chambers.

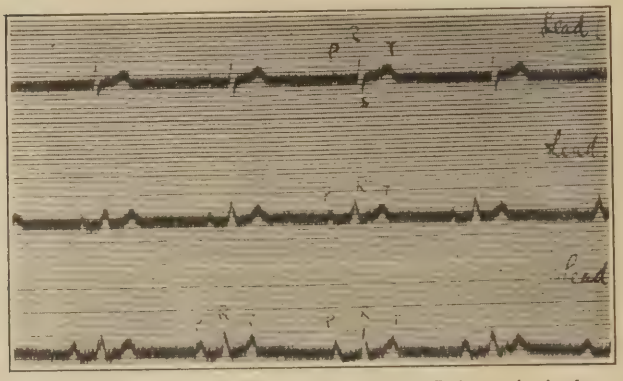

Fig. 2.—Vagal heart block; prolongation of P-R interval; the latter varies in length throughout the curves ranging from 0.22-0.28 sec.

was still imperfectly understood, and the current opinion continued to be accepted. In 1903 Osler (4) reviewed the whole subject, and published a series of cases of heart block. The intricate detail of his clinical observation was characteristic, also his deductions from the inperfect data of which he was then possessed. The pathology was lacking in some measure, however, for the minute anatomy of the heart was, at that time, undergoing revision and new facts with regard to its structure had not then received ample recognition. The now wellknown auriculoventricular bridge, described by Stanley Kent and His in 1893, was already attracting attention about that time; but its full function, structure, and ramifications were imperfectly divined until the publication of Tawara's description in 1906 which went far to simplify the existing conceptions. The later evolution of our knowledge with regard to heart block was largely aided by experimental study, in which context we might mention the work of Gaskell on the frog's heart, and that of Hering and Erlanger on the mammalian organ. The full appreciation of the whole subject, as we at present accept it, depends however upon the illuminating researches of modern observers, and especially would one mention the graphic studies by Lewis, Mackenzie and others.

Briefly we may summarize the outcome of all this combined evidence by recognizing the necessity of functional conductivity in the neuromuscular bundle which unites the upper and the lower chambers of the heart, and acknowledging this specialized tissue to be fundamentally essential to an associated action on the part of the auricles and ventricles.

By the term heart block therefore we define that condition in which the conductivity of the bundle is impaired, or wholly abolished; the causes which experience leads us to associate with such a happening include such conditions as the following:

1. Inflammatory exudation, hemorrhage, or cicatrization in the neighborhood of the bundle occurring during the course of acute infections, rheumatism, and such like maladies associated with pyrexia.

2. New formations, gummata, vascular growths, tumors and others.

3. Chronic interstitial fibrosis, the end result of long standing coronary sclerosis or actual thromboses; it would moreover be natural to assume that varying grades of block may be anticipated depending upon the intensity of the underlying pathological process, hence we appreciate the advantage of separating heart block into two main classes, a, the incomplete and b, the complete.

INCOMPLETE HEART BLOCK

In this condition the functional continuity of the auriculoventricular bundle, though depressed, is not wholly destroyed; the ventricle continues to be subservient to impulses from the auricle which descend by the normal route, the block as such being proclaimed by the undue length of time which the impulse takes in passing from the auricle to the ventricle (Fig. 3), and, at a more advanced stage, by the failure of certain impulses to reach and activate the ventricle. The former (delayed transmission) can rarely be recognized without instrumental aid, some graphic record which will inform us of the time elapsing between the onset of systole in auricle and ventricle, hence the value of noting the lengths of the a—c interval in the jugular curve (normally 0.2 second) and of the P. R. interval in the electrocardiogram (normally 0.14-0.18 second). Under certain circumstances we may suspect this early grade of heart block by auscultation alone; the auricular contraction may become audible by reason of its abnormal separation from that of the ventricle and, in so doing, give rise to reduplication or splitting of the first or second heart sound. For a similar reason the seat of murmur, if such be present in diastole, may undergo change of position in the cardiac cycle. The second variety, in which certain of the impulses fail to reach the ventricular chambers, is accompanied obviously by intermissions of beat and irregular bradycardia in varying degree; occasional intermissions are signalled by characteristic alterations in the grade of conduction of the bundle, thus we find that the ventricular silence is preceded by a gradual lengthening up to the time of the intermission, and it is usual to notice that, sub

sequent to this latter event, the passage of the stimulus to the ventricle is definitely facilitated. As the lesion progresses the intermissions become more frequent and simple ratios become established between the rates of the auricle and the ventricle, the latter responding to every second, third or fourth impulse from the upper chamber. The lesser grades of block are unlikely to be accompanied by any special symptoms, but the later stages are by no means so exempt. By reason of the tendency of the block to become complete from time to time we have cause to expect cerebral manifestations, transient giddiness, syncopal and epileptiform attacks, secondary no doubt to the temporary deficiency in the blood supply to the higher centres.

The progress of heart block from its incomplete stage to that we describe as complete is usually associated with excessively numerous cerebral seizures and we may reasonably expect the number of these latter to diminish somewhat when, with complete block established, the ventricle has definitely assumed its own inherent rhythm.

In conformity with the scale of irritability laid down for the cardiac musculature (5) we know that the idioventricular rhythm is extremely slow—usually about thirty a minute. Further, we realize, by clinical experience, that this low rate of beat is unstable and likely to be reduced without warning. It is at the times of further reduction in rate that the socalled cerebral manifestations of complete heartblock come about. A slowing of rate to 8 to 20 a minute will as a rule precipitate syncope, and a ventricular standstill of sixteen or more seconds will give rise to convulsions. Apart from these latter we must be prepared to recognize certain special phenomena in the general symptom complex of complete heartblock; the patient will complain of weakness, shortness of breath, giddiness and persistent fatigue in between the fits; he will notice that his field of response is very materially limited, and that even the slightest effort is likely to be fraught with serious results.

The normal heart rate accelerates in compensatory fashion as the result of exercise or effort and following the injection of atropine, or the inhalation of amyl nitrite. None of these influences have any appreciable effect on the idioventricular rhythm. Dispossessed almost entirely of its natural elasticity, the heart in cases of complete block becomes a highly inefficient organ; the slowness of the rhythm renders existence impossible except at the lowest vital level, and if this is not exceeded, the outlook need not be regarded in too gloomy a fashion. We know that the ventricular power, in the presence of heart block, is capable of dealing with the added strain which the long diastole and consequent overfilling impose upon the organ; the pulse pressure is exaggerated, the systolic reading is high,[1] and together these indicate strength of cardiac contraction and an adequate degree of filling and emptying on the part of the organ. Curves and tracings of complete heart block indicate the absolute dissociation

[1]In contradistinction one might refer to the bradycardia so frequently observed in cases of myxedema and hypothyroidism where, in consequence of functional sluggishness resulting from lowered basal metabolism, the pulse pressure is small, the systolic blood pressure low, and the volume outflow diminished.

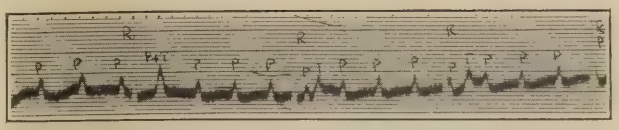

Fig. 4.—Complete heart block; note the regularly recurring auricular waves and the independent ventricular complexes.

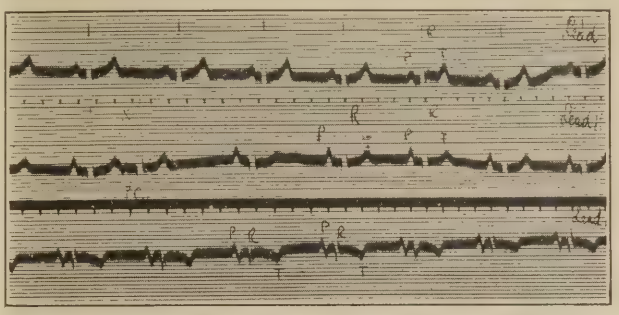

Fig. 5.—Bradycardia; normal sinus rhythm, disturbed at x in lead ii by the occurrence of a premature auricular contraction; the three curves taken together, especially the conformity of the Q.R.S. complex in lead iii, suggest a transversely placed heart.

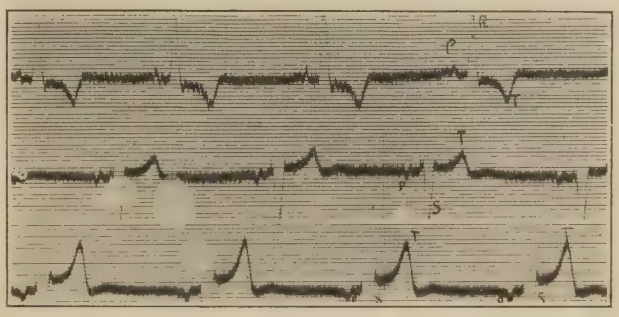

Fig. 6.—Sinus bradycardia; left ventricular preponderance.

between auricle and ventricle; the two chambers pursue their own rhythm in independent fashion, a fact that can usually be best appreciated by electrocardiograms (Fig. 4), but in certain instances we must expect difficulty in the differentiation between complete and incomplete block by these methods. It may seem that some varying degree of relation still exists between the auricular and ventricular contractions. In such circumstances we may try the effect of an inhalation of ammonia which will raise the auricular rate (6) but produce no effect upon the ventricular rhythm.

The next variety of intrinsic bradycardia to engage our attention is that associated with chronic myocardial degeneration. For the present purpose we need not separate the latter but, viewing degenerative processes in collective fashion, we may, with advantage, discuss the undoubted tendency to slow action which patients with advanced myocardial lesions are prone to evince.

As age advances a widespread tissue fibrosis tends to develop, and the reserve of elasticity and resilience becomes appreciably curtailed. The effect of this senile degenerative process upon the myocardium has been ably discussed by Wilson (7), and later Willius (8) has made interesting reference to the subject; the inferences of the latter observer led him to the following conclusion: "Diminished elasticity implies diminished amplitude of contraction favoring underfilling and decrease volume outflow. To favor greater filling of the heart, rate is slowed,

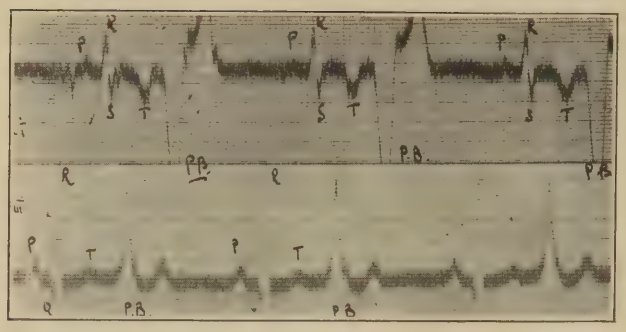

Fig. 7.—Arrhythmia of the coupled variety, each normal complex being followed by an atypical wave sequence (P.B.) indicating an ectopic impulse formation in the ventricular architecture.

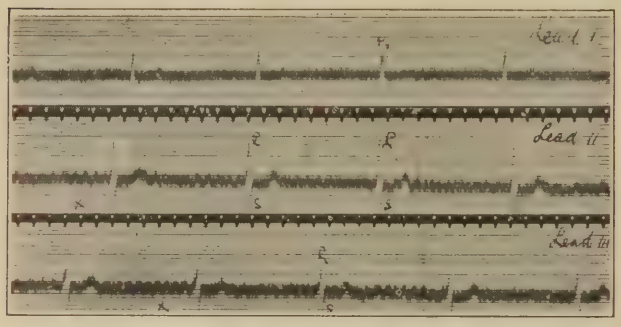

Fig. 8.—Bradycardia; note the absence of normal P. waves, also the regularity of the ventricular action, and the appearance from time to time (x,x) of regularly recurring and continuous oscillations indicative of auricular fibrillation.

thereby diastole prolonged. If this train of events progresses without increasing contraction amplitude, volume outflow becomes reduced to the point where the syndrome of cerebral anemia occurs. This reaction explains those cases presenting the Adams-Stokes syndrome unassociated with lesions of the auriculoventricular bundle and in which vagus augmentation is not present as determined by atropine response."

CITATION OF CASE MATERIAL

The brief notes of three cases at present under observation may be quoted in illustration.

Case II.—E. C., aged sixty-eight, male. Complained of giddiness, rapid exhaustion and inability for even moderate effort; circulation poor, felt the cold intensely and was unable to get pulse above 60. The physical signs were: Heart enlarged; rhythm irregular by reason of occasional premature contractions; sounds clear; no valvular disease; vessels thickened; blood pressure 180 systolic, 110 diastolic; jugular engorgement and hepatic stasis; the electrocardiogram showed a normal sequential rhythm at a rate of 60, with premature contractions left ventricular in type, and left sided preponderance. The reaction to effort was poor, and inhalation of amyl nitrite was without effect upon the heart rate. Myocardial degeneration and insufficiency were assumed.

The three cases are quoted as typical examples of bradycardia secondary to intrinsic degeneration of the cardiac musculature; one would especially remark upon the impoverished field of response in such types of patients, their tendency to elevation of blood pressure, the constancy of the slow action, and the lack of response to drugs which, under normal circumstances, produce an accelerated rate of beat.

In concluding our reference to bradycardia in association with myocardial degeneration a brief note must be inserted to deal with the comparatively rare form of the disorder which depends on a shift of the impulse formation from the sinus node to the junctional tissue.

The law of the cardiac musculature (5) assumes that the nodal tissues, from the point of view of inherent impulse formation, occupy a position between the moderately fast rhythm of the sinus node and the slow rate of the idioventricular rhythm; for obvious reasons therefore we may expect the junctional tissues to take over control of the cardiac rhythm if, for some cause, the sinoauricular node is in abeyance. Experimental investigation has assisted, in great measure, to develop our conception of nodal rhythm and our clinical deductions become proportionately more valuable. The condition as such was first recognized by Englemann (9) by means of the first Stannius ligature experiment in the frog, later produced by Lohmann (10) in the mammalian heart and finally confirmed by Meek and Eyster (11), who proved the automaticity of the auriculoventricular node by the method of initial activity. Our present conclusions with regard to the etiology of nodal bradycardia may be comprised under three headings (12):

1. Experimental nodal rhythm, as produced by cooling at the sinus region, stimulation of the vagus or accelerator nerves, forced respiration, or drugs including atropine, ether, digitalis, and veratrine.
2. Transitory nodal rhythm, as observed in acute diseases, diphtheria, scarlet fever, typhoid fever, or infective endocarditis.
3. Permanent nodal rhythm.

The clinical diagnosis of the condition will depend almost solely upon an interpretation of electrocardiographic curves; in these we find an altered relationship between the waves indicative of the respective activities of auricle and ventricle. As one would expect the upper and lower chambers receive their impulses more or less simultaneously if the node is directing the heart rhythm, whence we must be prepared to find R and P in abnormally close apposition; in point of fact the position of the P wave varies considerably, thus we may recognize it immediately before or after R, or on the other hand entirely submerged in this latter; in certain cases the position of P is noticed to vary from beat to beat, and it is suggested that this disturbance is due to a migration of the pacemaker within the actual confines of the nodal tissue (13).

The P wave moreover is usually abnormal in shape as a result of the ectopic focus of impulse formation, but the ventricular complex is of usual form for the stimulus passes downwards by the normal channels.

Premature contractions frequently distort the curves of nodal bradycardia, and we are safe in assuming that the actual foundation of the rhythm is extremely insecure. In this context we may refer to a case reported by Fussell and Wolferth (14) in which there was a constant shifting of the pacemaker back and forth between the sinus and auriculoventricular nodes, and when we consider that the rates of stimulus production in the two centres are

moderately close, it would seem likely that Laslett's (15) suggestion of variations in vagal tone as the important factor in the shift might very reasonably be adopted.

DIFFERENTIAL DIAGNOSIS

A considerable number of cases present no difficulty of any appreciable degree, and can be readily elucidated by simple methods; more especially does this apply to those types of bradycardia in which simple vagotonia happens for some reason to be established, for we can, at will, eliminate this inhibitory effect; but we must remember that complicated lesions are possible and that myocardial degenerative changes, heart block, enlargement, fatty degeneration, etc., are themselves sufficient to allow of and invite an increased vagal influence.

Though by no means essential in every case that comes before us, electrocardiography will prove of inestimable value in determining the possible intricacies which the slow heart beat presents; it enables an accurate understanding of the course and rate of propagation of the contractile wave in the cardiac musculature, points out abnormalities in the shape of bundle lesions, ventricular preponderance, diminished T waves, and other such evidence of myocardial degeneration, and incidentally defines irregularities of beat in decisive fashion. We may positively affirm that heart block in its early stages cannot be diagnosed without instrumental methods, and stress particularly the advisability for their usage in confirmation of the same event in its complete development; in this connection three cases may be mentioned where an alteration of rhythm was the chief physical sign.

Case III.—A healthy male, aged thirty, with no evidence of cardiovascular disease, whose only objective sign was a slow heart beat, irregular in that the rhythm was coupled; after exercise the rhythm became regular for a short period. The diagnosis seemed to rest between heart block, in which every third auricular impulse failed to reach the ventricles, and premature contractions alternating with each normal beat; the electrocardiogram (Fig. 7) showed that the latter was the correct interpretation.

Such[1] is a typical example illustrating that graphic methods go far to clear up the etiology of doubtful cases, and ably assist our ordinary routine methods of physical investigation; that these latter will need to be comprehensive is certainly obvious for bradycardia is known to be produced by so many widely differing states. We must endeavor to separate the neurogenic from those myogenic in type, and not forget in so doing that the latter are quite likely to be themselves accentuated by excessive inhibitory control; further we must attempt to estimate in some measure the significance, from the diagnostic point of view of the several members of the two main groups. This may be accomplished by a careful inquiry into the symptoms, the field of response to effort, the past history, and, what is perhaps even more important, the coexisting physical signs of disease such as acute infection, toxic poisoning, increased cranial pressure, or some of the other several lesions mentioned above. The specific diagnosis of bradycardia with an irregular rhythm will probably require the adoption of graphic methods, and heart block cannot be efficiently investigated without their aid. In conclusion, reference may be made to the value of atropine in the diagnosis of doubtful cases of bradycardia, the presence or absence of reaction following vagal release being, as was previously mentioned, of much practical worth in the correct appreciation of gross myocardial degenerative changes.

[1] Other cases cited by the author were omitted due to lack of space.

TREATMENT

In certain people the heart rate though naturally slow at rest is compatible with full health and vigorous vitality; obviously no treatment is indicated in these cases. Where, however, the condition renders itself significant active interference must be considered, and especially does this apply if the underlying cause can be elucidated. The simple bradycardia of convalescence may be treated on general lines which aim at raising the general nutrition, and incidentally that of the cardiac nerve trunks and musculature. Where toxins or extraneous poisons are in evidence an attempt should be made to antagonize their action or cut short their course, for we have observed how comparatively frequent is the bradycardia secondary to faulty innervation by irritation affecting the vagus nucleus, trunk or intracardiac endings. The correct treatment will depend upon the underlying cause in these types of cases, whether it be medullary poisoning by digitalis, bile salts, the toxins of uremia, or neuritis of the vagal trunk secondary to diphtheria, alcohol, lead or some such other cause in the same category.

Where the bradycardia is reflex in origin a good effect may follow the prescription of bromides, and if the condition is urgent we may have recourse to atropine or belladonna.

Antisyphilitic treatment in appropriate cases, e.g., myocardial degeneration and heart block, should be vigorously employed.

With evidence of raised tension, if this latter seems either causal or aggravating to the slowly beating heart, nitroglycerine, or the other nitrites should be given in trial doses; diffusible stimulants, camphor, alcohol, ether, ammonia, etc., should be given to counteract and ward off giddiness, faintness, and any tendency to an increase in the habitual slowing of the pulse.

Acute cases must be treated by general methods as for shock, complete rest with the head low, warm applications, caffeine, diffusible stimulants, atropine, etc.

Thyroid extract would appear to be indicated in cases of bradycardia by reason not only of the increased blood output per beat which it promotes, but also because it raises the rate of metabolism, and the threshold of myocardial irritability.

This drug may be worth a trial in such varieties of persistent bradycardia as are due to advanced myocardial degeneration, also in the presence of complete heart block, moreover the latter lesion does not contraindicate the prescription of digitalis or its allies; but one must admit that little indeed is the amount of tangible improvement in function that can be produced in the action of the ventricle when completely dissociated by disease from the upper chambers of the heart.

In conclusion we may mention the curative value of adrenaline and the beneficial effects which may result from the prescription of this drug in cases of bradycardia, heartblock, and similar conditions.

Phear and John Parkinson (16) have reported the notes and clinical details of a patient suffering from complete heartblock, whose seizures vanished entirely under adrenaline medication, and, assuming this to be due to stimulation of the sympathetic system, they quote in confirmation the evidence of experimental investigation which not only demonstrates the accelerating effect of adrenaline upon auricular and ventricular rhythms, but also would seem to prove that the drug has power to remove or modify heart block produced experimentally, and that therefore we possess in adrenaline an agent of the utmost value for the treatment of the ventricular standstill which determines the seizures of heart block.

The Significance and Consequences of Hypertension*

ERNST P. BOAS, M.D.,
New York

Although hypertension is one of the commonest conditions encountered by the physician in his practice, it is still one of the unsolved problems of medicine. Because of the fact that we are ignorant of its ultimate cause, the classification of the various disease entities, in which hypertension is the leading symptom, remains unsatisfactory. A clear understanding of the significance of hypertension must be based on a knowledge of the physiology of the cardiovascular apparatus, in particular of those factors which determine the level of the blood pressure and its variations. I shall, therefore, begin my remarks with a brief survey of the most important physiological factors that are concerned in the maintenance of the blood pressure.

With each systole, a part of the volume of blood ejected from the heart crowds out of the arterial system an equivalent amount of blood; the other part, finding no avenue for escape, distends the elastic wall of the aorta until it, in turn, can escape to the periphery. Because of its inherent elasticity, the stretched arterial wall tends to return to its original state, it is under tension. This is known as the arterial tension and is equivalent to the pressure of the blood within the vessel. Thus the arterial tension and the blood pressure represent the same force. The greater the resistance to the outflow of blood to the periphery, the greater will be the distention of the large vessels, so that one may say with Lauder Brunton that "the arterial tension results from the difference between the amount of blood discharged from the heart into the arterial system, and that which passes from the arterioles into the veins" and with Marey that "the arterial tension is a force created by the ventricular contraction, maintained by the reaction of the bloodvessel walls to their distention, and regulated by the resistances offered by the peripheral vessels to the outflow of blood."

It is apparent, therefore, that the blood pressure is determined by a number of factors: the systolic output and the rate of the heart, these two together giving the minute volume output of the heart; the elasticity of the arteries; the peripheral resistance; the volume of the blood in the whole arterial system and the viscosity of the blood. Because of the intermittent pumping action of the heart, one must further distinguish between the systolic and the diastolic blood pressures. During systole, the phase of cardiac ejection, there is a sudden rise in the blood pressure. This is known as the systolic blood pressure. It is determined chiefly by two factors, the volume output of the heart, and the elasticity of the large arteries. During the diastole of the heart no blood is being forced into the aorta. On the contrary, blood is constantly flowing to the periphery and from the arterioles into the venous system. The pressure within the vessels during this phase is known as the diastolic blood pressure. It is determined chiefly by the peripheral resistance to the outflow of the blood. The peripheral resistance is determined by the tone or state of contraction of the arterioles and probably of the capillaries as well.

With each systole, the heart, in order to open the semilunar valves and discharge its contents into the aorta, must generate a force greater than that represented by the diastolic blood pressure. The latter, therefore, is a measure of the constant load under which the heart is laboring. The systolic pressure is a measure of the force resultant from the volume of the cardiac ejection and the elasticity of the large arteries. It is important, therefore, in all blood pressure studies, to record both the systolic and diastolic pressures in order to obtain a complete understanding of this aspect of the dynamics of the circulation.

It is selfevident from this analysis of the factors that determine the blood pressure that in any person it is not a constant static force, but that it varies from moment to moment, depending on the variations in the elements that determine it. Thus, it is well known that the systolic output of the heart, as well as the heart rate, are constantly changing and that the peripheral resistance is likewise variable. Consequently the blood pressure too is constantly undergoing alterations of level. Most of these are strictly physiological adaptations of the circulatory apparatus to the needs of the body. A thorough understanding of these variations and of the phenomena by which they are determined is essential to an intelligent evaluation of sphygmomanometric readings in the clinic.

It will be found in the majority of cases that when repeated blood pressure estimations are made at short intervals, the later readings show a lower systolic pressure than the earlier ones. The difference between the first and the last readings in a normal individual may be as much as 30 mm. The final read-

*Read before the New York Physicians' Association, April 23, 1924.

ing, when the pressure has become established, is the most accurate measure of the blood pressure and is called the residual pressure. Ordinarily four or five readings in the course of ten minutes are sufficient to determine the residual pressure. There are two causes for this phenomenon. First, the general excitement or apprehension of the patient, or slight bodily exertion preceding the test, will cause a general elevation of the blood pressure. Second, as MacWilliam and Kesson have shown, if the artery is in a state of contraction, it will offer considerable resistance to compression by the air cuff and thus give a false high reading. Repeated compression, however, will relax the vessel, so that the final readings will be lower and more representative of the true arterial pressure. The importance of local vasomotor reactions has been demonstrated by Galli, who found that when the cuff was inflated with hot air, alternating with cold air, the blood pressure sometimes varied by 40 mm. Addis has brought out clearly the degree of variation of blood pressure that may occur under different environmental conditions. He measured the blood pressure in a series of normal young men first early in the morning, when they awakened, and before they arose (basal conditions), and then during the day when they were quietly up and about. The averages were: under basal conditions 99/71; in the day time 127/78. Arteriosclerosis rarely is of sufficient degree to interfere with the accuracy of the readings. If the artery is completely calcified, as in a case that recently came under my observation, it may be impossible to obliterate the vessel.

The difference between the systolic and diastolic pressures is known as the pulse pressure. Thus, if the blood pressure is 120/80, the pulse pressure is 40. Normally the systolic and diastolic pressures bear a certain relationship to one another, and therefore the pulse pressure, as an expression of this relationship, is of value. The following formulas give a rough and ready appproximation of this correlation:

$$\text{Diastolic pressure} = \frac{\text{systolic pressure}}{2} + 10$$

In cases of marked hypertension one must add 20 to the right side of the equation:

$$\text{Diastolic pressure} = \frac{\text{systolic pressure}}{2} + 20$$

Marked variations from this ratio are significant of the operation of some pathological factor and are of value in diagnosis.

As a practical illustration let us take three patients all of whom have the same systolic pressure, but different diastolic pressures. Here is one whose pressure readings are 160/90. This represents a slight hypertension with a normal relationship between systolic and diastolic pressures, according to our formula. The readings of the next one are 160/120. Here we have a very high diastolic reading accompanied by a systolic reading that is relatively low. It represents, as we shall see later on, a patient with marked hypertension whose heart has become insufficient. The third patient has a reading of 160/50. He has aortic insufficiency, with only a systolic hypertension from the increased cardiac output and a low diastolic pressure. If we had used the systolic pressure alone as a guide, the essential differences between the cardiovascular disorders of these three patients would have escaped us. Yet each patient demands different treatment.

Many attempts have been made to arrive at figures representing the normal range of blood pressure in adults. The difficulties bound up with such an attempt are manifold. It is necessary to accumulate a very large number of readings which means that many examiners must contribute their observations. This introduces the factor of the variability of the measurements by different individuals, as well as those due to the fact that the readings are not taken under absolutely uniform conditions. A survey of all of the work that has been done along these lines makes it appear that for practical purposes we may accept a systolic pressure of 130 for men and 127 for women, as the upper limit of normal. In patients over fifty-five years of age, 140 may be considered as the upper limit of normal. For the diastolic pressure 90 may be taken as the maximum figure for normal adults. It is apparent therefore that the former view that the blood pressure advances significantly with the age of the patient, which gave rise to the formula that the blood pressure at any age may be arrived at by adding 100 to the age in years is inaccurate. The rise with age is real but it is slight. Interesting as well as significant is the observation of Symonds that in all age groups the heavier subjects on the average have higher blood pressures.

Of what practical value to us as practising physicians is a knowledge of the facts which we have been discussing. One of the most important points is the demonstration of the variability of the blood pressure and the necessity for determining the residual pressure as the true pressure. This simple precaution will prevent us from assuming the presence of hypertension when it does not exist, and will make us cautious in interpreting drops in pressure reaching even as high as 25 mm. as significant and attributable to the particular therapeutic regimen we may happen to have prescribed in a specific case.

Assuming then that we have taken all of these facts into consideration, and that the patient presents a real elevation in blood pressure. What is the significance of such a finding? The question as I have put it is too simple. Before we can give an answer, we must know whether it is the systolic or the diastolic pressures or both that are abnormal. We must know whether the elevation is temporary or permanent; we must know something about the condition of the heart and arteries.

Systolic hypertension.—By this term we mean an elevation of the systolic pressure with little alteration of the diastolic pressure. An increased output of the heart, by increasing the elastic distention of the wall of the aorta, will elevate the systolic blood pressure. The diastolic pressure will remain unchanged unless there is an alteration of the peripheral resistance. Such a condition is seen after exercise and in patients with exophthalmic goitre. In aortic insufficiency the volume of the systolic ejection is increased because of the leaking valve, and here, too, one observes a high systolic pressure, but because of general dynamic changes in the blood circulation, diastolic pressure in these cases is abnormally low.

On the other hand, a loss of elasticity of the aorta

and the large vessels derived from it will also tend to elevate the systolic pressure and leave the diastolic pressure undisturbed. In this case the aorta cannot distend to accommodate the volume of blood ejected from the heart, it has no give. As a consequence with systole the pressure within the aorta suddenly rises very steeply, the blood is rapidly forced to the periphery, so that the pressure rapidly falls and the diastolic pressure is unchanged or even low. Thus extensive atherosclerosis of the aorta, which is so common in older individuals, is often accompanied by a raised systolic pressure with a normal diastolic pressure. The fact has not received sufficient attention and is worthy of note.

Similar readings may be obtained in certain patients with bradycardia. The long diastole allows a greater amount of blood to flow from the arteries to the veins, the arteries become comparatively empty and, consequently, the diastolic pressure is low. The systolic pressure is unchanged. For instance, in a patient with complete heart block and a rate of 40, but no valvular lesion, the blood pressure was 130/40. In another patient in whom periods of block alternated with periods of normal rhythm the pressure, when the rate was 76, was 200/100, when the rate was 36 it was 200/70. The last reading is identical with what we have called systolic hypertension; although its mechanism is quite different, it is really a diastolic hypotension.

Transient hypertension.—Transient hypertension may be due to vascular crises, as they were called by Pal, or may be of sufficiently long duration, that the term crisis is no longer applicable. Some of the diseases commonly associated with transient hypertension are certain forms of angina pectoris, tabes dorsalis, eclampsia, and lead poisoning. In all of these conditions the high pressure is paroxysmal, accompanying an acute attack of angina, a gastric crisis, an eclamptic seizure, or lead colic. In the intervals between the attacks the pressure is normal. It is evident that in these cases the sudden elevation of pressure is determined by a constriction of the peripheral vascular bed. Increase in pressure will therefore be manifest in both systolic and diastolic pressures.

Acute nephritis, particularly glomerulonephritis, such as is seen following scarlatina, is usually accompanied by a rise in both systolic and diastolic pressures. The same holds true of the toxic nephritides of pregnancy. Most of these patients recover completely from their nephritis and with this the blood pressure sinks to normal.

Persistent hypertension.—Here we have quite a different picture. Under this caption come patients with socalled essential hypertension, and with the hypertension accompanying chronic nephritis. Although in isolated cases the vascular pressure relationships may return to normal, such a sequence is the exception, not the rule, so that as a descriptive term, we may use "persistent hypertension."

Let us first turn our attention to that class of patients who are conventionally classed under the category of essential hypertension. They form by far the largest group of all patients with elevated blood pressure. Of the ultimate cause of their disorder we are largely ignorant, but we have learned a good deal about the natural history of their disease. As I shall endeavor to show their primary physiological disturbance, and in them the functional disorder long precedes any anatomical changes in the organs of the body, consists of a narrowing of the peripheral vascular bed, due to an increased state of contraction of the arterioles and possibly of the capillaries. This arteriolar contraction may be visualized as an increased state of tonus in which the arterioles, although anatomically normal, are set, so to speak, in the position of partial contraction. Yet with this their sensitivity or that of the nerves that control them is greatly increased, so that they undergo great variations in calibre under altered environmental conditions. This variation of calibre results in a parallel variation of the peripheral resistance, and so leads to a marked instability of the blood pressure.

The clinical picture then of a patient with early essential hypertension can be readily visualized. The patient who has usually passed his forty-fifth year is often overweight because, for some undetermined reason, hypertension is associated with obesity; in women the condition is often discovered at the menopause. The hypertension which is usually discovered accidentally, is of no very great degree, maybe 175/95. There is no cardiac enlargement and no evidence whatsoever of renal disturbance. If we observe such a patient over a long period of time, possibly for months or years, and if we measure his blood pressure at different times of day under varying conditions, we shall learn that it is undergoing constant and great fluctuations. Early in the morning the pressure is apt to be low; in the afternoon it is high. Emotional upsets and mental strains are quickly reflected in a rise in pressure. It is the systolic pressure in particular that is labile. It is in these patients that we see apparent cures with particular frequency. We find that under treatment, or following an acute intercurrent infection, the pressure at times returns to normal. But in many such cases the drop is only temporary. In the course of weeks and months the pressure again rises and the former clinical picture is repeated.

This state of affairs may continue for five, ten or even twenty years without much change and with few symptoms. More often, however, there is a slow but steady tendency of the pressure to rise to higher levels. With this it gradually becomes more stable; the fluctuations are no longer so extreme and normal figures are rarely approached. It is at this stage that we see diastolic readings of 105 and over and systolic readings over 200. Now the patient has arrived at the stage of fully developed hypertension, as we usually think of it. Hypertrophy and dilatation of the heart, with possibly relative mitral insufficiency, have become manifest, and certain subjective complaints have put in an appearance. Most important among these are headache, vertigo, shortness of breath, and possibly slight swelling of the feet. Even with this degree of hypertension the patient may survive many years.

Let us again ask, "What is the significance, and what are the consequences of such a hypertension?" The true significance of a persistently elevated blood pressure is still ill understood. Of its immediate cause we know very little. That hereditary factors play a very important rôle is becoming more and more apparent. Weitz has recently published a very interesting study of the families of eighty-two pa-

tients with hypertension. He found that in these families deaths from apoplexy or heart failure among the parents of the persons examined were much more common than in a control series; and that the parents of the hypertension series died at an earlier age, indeed few of them reached old age. He measured the blood pressure of ninety-three brothers and sisters of forty-two patients with hypertension and found in them a much higher percentage of hypertension than in a series of random controls. Of the brothers and sisters who were over fifty-five years of age, fully one half either had hypertension or had already died from its effects. We all have encountered instances of familial hypertension, but this study of Weitz adds a new significance to such chance observations. There must be some form of hereditary constitutional predisposition.

Aside from this factor, and from those isolated but suggestive cases of hypertension associated with a disorder of one of the glands of internal secretion, our understanding of the cause of hypertension is still very much circumscribed. We have learned, however, that many factors which were formerly held responsible for hypertension have nothing to do with its causation.

Atherosclerosis, sclerosis of the larger arteries, stands in no constant relationship to high blood pressure. Commonly, patients with the most advanced changes in the aorta, coronaries, and large peripheral arteries have normal or even low blood pressures. Some will show the systolic form of hypertension which we mentioned earlier in our discussion, but this is of an altogether different character. On the other hand, disease of the arterioles is an almost constant accompaniment of long standing hypertension. We do not, however, regard this arteriolosclerosis as the cause but rather as an effect of the elevated blood pressure. The arteries of these patients are undoubtedly under a much greater strain than those of normal persons. They react to this strain first by hypertrophy. In vessels of the elastic type it is the elastic tissue that increases in amount; in vessels of the muscular type it is the muscular media that hypertrophies. These changes are followed by secondary degenerative changes which may result in markedly diseased arterioles and interference with the blood supply of the tissue nourished by them. Yet this arteriolar disease is not universal; the vessels of the cutis and of the skeletal muscles suffer little damage. It is the arterioles of the kidney, spleen and pancreas and less often those of the intestine that are involved in this process. There must be added local factors which determine the selective localization of the arteriolar lesions.

This leads us to a consideration of the relationship of kidney disease to hypertension. In the cases of essential hypertension which are under discussion kidney damage is as a rule of little clinical importance. It is true that in almost every case some of the arterioles show sclerotic changes with subsequent fibrous replacement of the glomeruli which they supply, as well as of the tubules supplied by the efferent arteriole of the glomerulus, but in most instances there is so much healthy kidney tissue left, the margin of safety is so great, that the lesions are of no clinical importance. Moreover, the scarring of the kidney progresses so slowly that in most cases long before enough kidney tissue is destroyed to jeopardize the life of the patient, he has succumbed to cardiac failure or to cerebral hemorrhage. In few instances the loss of kidney substance is of sufficient degree to cause uremia and death.

The point which I wish to emphasize in particular is that the kidney lesions in these cases have nothing to do with the causation of the hypertension. They are the effects of the arteriolar changes which accompany hypertension and may be lacking in early cases. What then is meant by the term "nephritic hypertension," which we hear at every hand? To me it seems very doubtful that kidney disease is very often the determining cause of hypertension. But there are many cases in which kidney insufficiency is associated with hypertension. Among these there are the cases of malignant kidney sclerosis of the German authors and of chronic glomerulonephritis. They differ from the cases of essential hypertension in several important respects. The patients are, as a rule, younger. They are in their fourth and fifth decades, occasionally they are still in their twenties. The disease progresses much more rapidly to a fatal issue. Within one, two or three years death from uremia follows. As a rule the blood pressure is higher in this group of patients than in the preceding one and is more stable. Yet it is very unlikely that the hypertension in these cases is secondary to the kidney disease. Most probably it is determined by the same factor which determines the rapidly advancing arteriolar changes and the secondary destructive changes in the kidney. As a matter of fact, occasionally one sees patients with true uremia, in whom the blood pressure is not elevated.

More puzzling, on the other hand, are certain cases in which it seems quite clear the kidney insufficiency is primary, but in which hypertension and cardiac hypertrophy may develop to a marked degree. This obtains particularly in patients with congenital polycystic kidneys, in whom the terminal picture with uremia and hypertension may resemble closely that of chronic nephritis with hypertension. Other forms of kidney insufficiency, for instance, suppression of kidney function following compression of the ureters by new growths, or extensive loss of substance from pyelonephrosis or hydronephrosis, may be accompanied by hypertension. It seems hard to avoid the conclusion that in these cases the hypertension is really secondary to the kidney disturbance. Here, too, we may class the lesser degrees of hypertension that accompany the urinary obstruction of prostatic hypertrophy, which clear up when the local condition is relieved.

Does the blood pressure ever return to normal in these cases of advanced hypertension, particularly in those patients with advanced kidney changes and arteriolar disease? I am aware that many hold this belief and indeed take for granted that when severe myocardial insufficiency sets in, the blood pressure must drop to low figures. A corollary to this view is the assumption when one discovers a large heart without valvular defects in a patient with normal blood pressure, that the individual in question formerly suffered from hypertension. I am always sceptical when this interpretation is offered.

Careful observation will establish the fact that in by far the vast majority of patients with hyperten-

sion, the onset of severe myocardial insufficiency is followed by a fall of some 20 to 40 mm. in the systolic pressure with no alteration or with even a rise in the diastolic pressure. When we recall the factors that are responsible for the maintenance of the blood pressure, when we remember that the systolic pressure is determined largely by the systolic ejection from the heart, and that the diastolic pressure is determined chiefly by the peripheral resistance, and that it represents the constant load to which the heart is subjected, we are in a position to understand this phenomenon. When the myocardium weakens, the systolic output will diminish and, therefore, the systolic pressure will be lowered, but this does not of necessity affect the tonus of the peripheral arterioles which determines the diastolic pressure. As a matter of fact, the increased carbon dioxide content, or the diminished oxygen saturation of the blood or both stimulate the vasomotor centre and tend to elevate the blood pressure. That is why in certain patients with mitral disease or with emphysema, we find a moderate elevation of the blood pressure when the heart is insufficient, which drops to normal as the patient improves.

It is true that at times a blood pressure which has been persistently high returns to normal levels. A blood pressure of 200/110 may drop to 125/70. In a case recently studied at Montefiore Hospital the pressure was followed for two and one half years. In October, 1921, it was 210/110, in July, 1923, 135/68, but six months later it had again risen to 170/104 and shortly before the patient's death in February, 1924, it was 160/94.. As you see, in this case the pressure became lower but did not become normal. A marked drop in diastolic pressure is not due to cardiac failure but to a diminution in a loss of the influence which determined the increased tone.

The organs that suffer most frequently and most severely from the effects of persistent hypertension are the heart and the brain. Indeed, it is the rule for subjects of hypertension to die of cardiac failure, or of cerebral hemorrhage or thrombosis. Uremia is a rare termination.

With persistent hypertension, cardiac enlargement occurs very soon. Indeed, in acute nephritis with hypertension it may develop within a few weeks. Hypertrophy may in the course of time reach extreme degrees. Pathologically these hearts are characterized by little organic change, except an increase in the muscle mass and a slight increase in the interstitial connective tissue. Gross scars of myocardial degeneration following coronary occlusion occur, but are not characteristic. As a rule there is a marked discrepancy between the anatomical lesion and the degree of myocardial insufficiency. A patient may die of a failing heart, yet the pathologist may find the heart muscle in apparently good condition. Myocardial degeneration should not be rashly diagnosed in patients with hypertension. Here the electrocardiograph may be of distinct value.

I wish to dwell on only a few symptoms that accompany cardiac failure in patients with hypertension. The blood pressure reaction we have already discussed. With this there usually appears a typical gallop rhythm at the apex which is practically pathognomonic of weakness of the cardiac muscle. In the first stage of cardiac insufficiency it may appear only after slight exercise. The second important symptom of grave circulatory insufficiency which is seen with particular frequency in patients with hypertension is pulsus alternans. This would be observed more often if it were looked for more carefully. It is not necessary to employ a polygraph to detect its presence in most cases. In the more advanced stages it can be noted by simple palpation of the pulse. In doubtful cases it may at times be brought out by slight compression of the brachial artery with one hand, while palpating the pulse at the wrist with the other. Finally, alternation can be readily detected by means of the sphygmomanometer. One measures the blood pressure in the ordinary way, but releases the air from the cuff very slowly. If alternation is present one will find that the strong beats come through at a higher level of pressure than the weak ones. If, for instance, the pulse rate is 90, one may, at a pressure of 160 mm. hear the strong beats, but since only every other beat is a forceful one, the pulse rate will be halved, that is, to 45. On releasing the pressure still further, one will at a level of say 135 mm. hear both the strong and the weak beats and the full pulse rate of 90 will be perceived.

Cerebral hemorrhage or thrombosis is another very common sequel of hypertension. About two thirds of all patients with hemiplegia have hypertension. The development of a cerebral insult ordinarily exerts no effect on the blood pressure. It is of interest to note that patients with hypertension and hemiplegia, unless they are subjects of coronary artery disease, rarely die from cardiac failure. This is due, I believe, to the fact that their paralysis cripples them to such an extent that the heart is spared the strains and compensatory adjustments demanded by the exigencies and activities of everyday life. In other words, the patients are undergoing an enforced rest cure. Death in these cases is due either to further cerebral insults or to a complicating illness.

A word about the retinal changes in patients with hypertension may be of interest. Albuminuric retinitis, and the other changes described in these patients, may be traced directly to disease of the capillaries and arterioles of the retina. This arteriolar disease is the same as we see in the other organs of the body in hypertension. In essential hypertension we found a slowly progressing sclerosis of the arterioles in the kidney, pancreas and spleen. A similar change of the retinal vessels will account for the milder degrees of retinal change that are observed. We found that in the socalled malignant scleroses and in the chronic glomerulonephritides the arteriolar changes were more rapidly progressive and more severe. It is in these cases that we see the more advanced changes of albuminuric retinitis. In view of its pathogenesis you will understand that the term albuminuric retinitis is a misnomer, for the retinal picture is the result not of a toxic injury, but of the general arteriolar disease.

In this sketchy review of the subject of hypertension I have tried to emphasize only a few points. First, that a knowledge of the physiology and pathology of the cardiovascular system enables us to get a clearer and more rational picture of the disturbances of the blood pressure; and second, that hypertension is a manifestation of disease of the whole cardiovascular apparatus and not of the kidney alone.

Mitral Stenosis

LOUIS FAUGERES BISHOP, M.D., Sc.D., F.A.C.P.,
New York

I venture to assert that the physical signs of mitral stenosis constitute an essentially difficult problem. No one, I am sure, can deny that a vivid description of physical signs which is easy to write is equally difficult to comprehend and fit to an individual example of the disease. If one could eliminate the occasional person presenting signs as they ought to be, it would be easier to believe how often many signs do not exist or cannot be found. In many examples of this condition a careful consideration of a skilfully taken history is of great importance, particularly a history of spitting of blood, which is present in a surprising number of cases.

The murmurs to be studied in mitral stenosis are, of course, those heard during diastole, when the blood current is going forward through the mitral orifice. This period should be divided into three parts in the mind and each part listened to with attention. As the heart relaxes the onward flow of the blood from the veins constitutes a current through the mitral orifice. How much noise this current makes depends upon the condition of the orifice and the conduction of the sound. The point is to bear in mind that this current of blood flowing into the heart is what must make the murmur of mitral stenosis. When the auricle comes into action, as it does when it is not fibrillating, it gives an additional push to this current so that the blood is moved faster, until the impulse that started in the auricle has traveled to the ventricle which contracts and reverses the current. If the valves are intact this reversal of the current closes the valves. If the valves are out of order the current flows backward into the auricle.

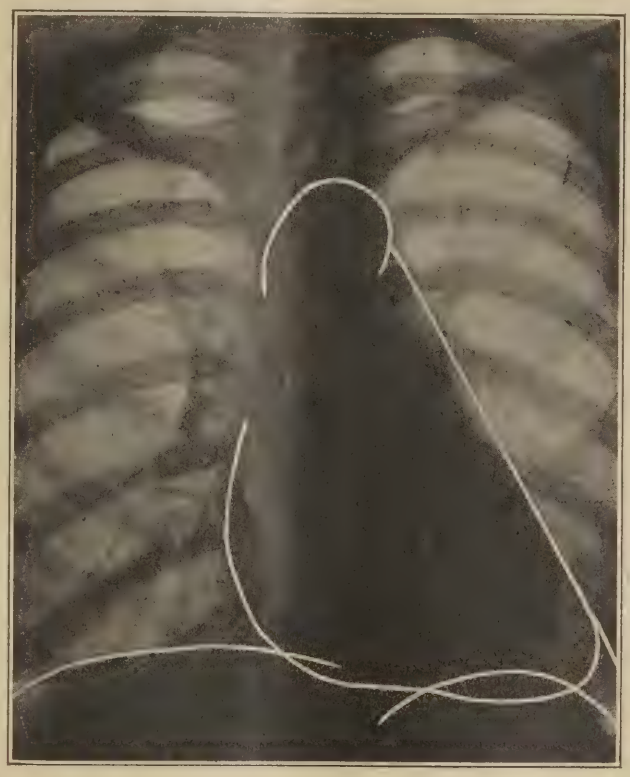

Fig. 1.—X ray of the heart in mitral stenosis

Our task in auscultation is to listen to see if any sound is being made. If we hear a noise we call it a murmur. Often enough there is no noise. The noise that we would expect from what we have said is a soft continuous sound during the whole of the diastole, with an increased sound when the auricle contracts and forces the blood more rapidly into the ventricle. It must be realized that the action of the auricle is not in any sense comparable with the action of the ventricle. The auricle has no valves to prevent the regurgitation of blood into the veins and its work is not an essential one, as is proved by the very effective action of the heart when the auricle is paralyzed.

The ventricle may be said to pick up the blood at a standstill and move it to a definite place beyond, as if a man stepped out on a road and picked up a load and carried it a block and laid it down. The auricle gives an additional push to the load that is already being carried forward by the push of the pressure in the veins and the suction of the expanding heart. The auricle is like a man standing at the side of a road administering a push to someone carrying a load forward from some place back.

This picture makes it quite clear why the murmurs of mitral stenosis are so uncertain and indefinite as compared with the murmurs that are produced through systole of the ventricle. If the expansion of the heart is very definite and the pressure in the veins is relatively high we get a diastolic murmur throughout the diastole. If the auricle is acting we get a sharp sound during the last half of diastole as the auricle administers its push to the passing stream. If the auricle is paralyzed the noise is often loudest when the current has had time to get under way and before it is checked by the commencing contraction of the ventricle. Hence we get a middiastolic murmur.

Sometimes when the expansion of the heart is very definite and the pressure in the veins very slight, we get a sound very early in diastole and no particular sound during the middle or end of the period. These sounds are limited in their amount of conduction and are often found to cover just about as much space as can be covered by the end of the stethoscope. They should be looked for a little above and within the apex.

Ten thousand doctors ten thousand times have described murmurs, but no one yet has been able to take the personal equation out of the matter. Hence it is a subject that cannot be asborbed second hand, for every man must work out his own interpretation of what he hears, being assured that he does not hear the same thing as the man ahead of him or the man behind him.

The subject of interpretation of murmurs lends

itself to fine writing and lecturing, but I hear almost every day of some great clinician who has abandoned his dogmatic attitude of former years, which was forced upon him by the popular opinion that a great doctor, and he alone, could hear and interpret heart murmurs. It is fortunate that modern cardiology has come along to give us new methods just at a time when the high priests of medicine have lost their faith in murmurs.

Quinidine Sulphate in Auricular Fibrillation

Its Administration in Private Practice

S. NEUHOF, M.D.,

New York

Since quinidine first came into general use a few years ago because of its extraordinary power to restore the normal rhythm in a fair proportion of cases of auricular fibrillation, there have been many case reports and a few experimental studies dealing with the fundamental method of its action. In an excellent paper dealing with the latter, Lewis and his coworkers (1) draw the following conclusions regarding the effect of quinidine sulphate in auricular fibrillation in man. They state that the drug has two actions: first, directly upon the cardiac musculature by which it lowers the sinoauricular rate; depresses and prolongs conduction time from auricle to ventricle; and, most important, it lengthens the refractory period of the auricular musculature. Second, it causes partial paralysis or release of the vagus; in this, it resembles atropine and differs from digitalis, which increases vagus inhibition.

Auricular fibrillation is now regarded as basically due to irregular blocking of a continuous circus wave of excitation, the normal method of the spread of impulses through the auricles. Although the circus wave still continues, blocking of it depends upon differences and defects in conductivity and irritability of various portions of the auricular musculature. The consequence is what we clinically know as auricular fibrillation.

Before normal rhythm is restored by quinidine, there is usually a preliminary stage of rapid heart action, with or without restoration of the normal rhythm. Occasionally the tachycardia becomes violent. This, and the fact that quinidine can cause gastrointestinal disturbances—nausea, vomiting and diarrhea—and occasionally cerebral embolism from slowing of the auricular blood flow coincident with the restoration of normal rhythm, have up to the present practically limited the use of the drug to hospital cases. To emphasize the danger, there is a recent report of a case of auricular fibrillation in a patient with mitral regurgitation who was given eight grains of quinidine daily for three successive days. In all twenty-four grains were given. On the second and especially the third day, there was evidence of severe decompensation with auricular fibrillation still present. It took thorough digitalization slowly to restore compensation. This indicates that there exists a drug idiosyncrasy to quinidine in some individuals, as indeed is true of all powerful drugs. Quinidine undoubtedly increases the tendency to decompensation or actually causes heart failure by its occasional action in causing marked increased ventricular rapidity.

I have had occasion to use quinidine sulphate in hospital practice in some forty patients with auricular fibrillation in all types of cardiovascular disease. Many of the patients were old persons with marked cardiovascular and cardiorenal changes, some with, others without, hypertension. Many were decompensated. The net result of quinidine administration was temporary restoration of normal rhythm in a few of these patients. A few complained of nausea. One or two vomited. Several exhibited an increase of tachycardia, but none to any alarming extent. Some of the patients had two or three courses of quinidine, but the results were the same. All of the patients were properly digitalized before the quinidine was given. I had not expected permanent restoration of the rhythm in these advanced cases of cardiosclerotic disease, for it was my clinical impression that quinidine was of value chiefly in younger persons without far advanced degeneration of the heart muscle, in other words, mainly those with valvular disease. My routine administration consisted in first giving one five grain probatory evening dose of quinidine sulphate. If the next day there was no evidence of idiosyncrasy and no untoward symptom—no vomiting, diarrhea or undue tachycardia—three other five grain doses an hour apart were administered in the morning. The patient was again examined. If fibrillation had not stopped or there was no contraindication, especially no significant increase of tachycardia, three more five grain doses of quinidine an hour apart were given on the succeeding day. Thus, altogether thirty grains were given.

I have found this method and amount satisfactory, and up to the present have not noticed any ill effects from the doses as such. It seems safe because any important drug idiosyncrasy will show itself after the first five or certainly after twenty grains, a dose which seems well within safe limits.

Because I consider quinidine a drug that should have the widest use in appropriate cases, and not be confined to hospital cases alone (indeed, it has recently been used in ambulatory cases) (2), I began the use of the drug in patients who were at home under the care of their private physicians. These were men of average ability, most of whom

had no special knowledge of cardiac disease. Where indicated the patient was first digitalized. Quinidine was given as already outlined, and the physician was told to visit the patient after the first, third and final doses. The special possible dangers to be looked for were pointed out. Not more than a total of thirty grains was administered. The physician then reported to me. I feel that if this method is carried out, the drug may be administered by the medical attendant almost as safely and as well as if the patient is under the control of a cardiologist in a hospital.

The following cases were treated by the family physician after consultation:

Case I.—J. R., aged fifty-two, gave no history of infection except rather frequent colds in the head. Twenty years ago, his insurance rating was normal. Six years ago, he was rated up. He is of an excitable though not worrisome temperament. Examination revealed a typical mitral stenotic lesion with auricular fibrillation. The latter was confirmed by electrocardiograms. The fluoroscope revealed a dilated aorta and an enlarged heart. He was returned to the care of his physician. Because of the tachycardia, he was first digitalized; twelve digitan tablets in three days were given. This reduced the cardiac rate to within normal limits. The quinidine sulphate therapy by the method above outlined, was instituted. This had no effect upon the rhythm, nor did it produce any gastric or intestinal disturbances or unwonted tachycardia.

Ten days later, quinidine sulphate was again given, but this time a total of forty grains were administered; that is, five grains hourly for four doses, then a visit by the physician, and again four hourly doses of five grains each. This dose likewise had no effect upon the rhythm, nor did it cause any untoward symptom.

Case II.—Mrs. C., aged forty-eight, patient of Dr. D., gave a typical rheumatic history. She knew of her heart lesion for at least eleven years. Her menses stopped one year ago. From the patient's history, it seemed probable that the onset of auricular fibrillation occurred as the result of climbing eight flights of stairs in an office building, followed by some excitement at home. Frequent digitalization, rest in bed, and sedatives had no effect upon the arrhythmia or upon the cardiac rate. Examination revealed typical mitral, probably also aortic stenosis, with auricular fibrillation. The latter was confirmed by electrocardiograms. The orthodiascope revealed a heart enlarged to the right and left. In addition to the quinidine sulphate routine, the patient's physician was advised to give luminal tablets, each containing one and one half grains, twice on the day before the quinidine therapy. The physician reported that normal rhythm was restored and remained so for two days, then fibrillation again set in. Quinidine was again advised. A later report from the doctor stated that except for occasional extrasystoles the rhythm has remained normal for several months. She is fully compensated, is able to follow her household duties and feels comfortable in every way.

Case III.—H.D., male, aged thirty-nine, patient of Dr. K., had chorea when eleven years old. He had had socalled heart trouble for years. Examination showed a typical mitral stenotic lesion with auricular fibrillation. The latter was confirmed by electrocardiograms. X ray showed that the heart was enlarged to the right and left. The patient's physician was advised how to administer the quinidine sulphate. The medication caused no deleterious effect. It had no effect upon the rhythm.

Case IV.—A. G., aged fifty-seven, patient of Dr. W., had much work and stair climbing to do. She had had frequent attacks of bronchitis and shortness of breath in previous years. Her climacteric began two years ago with menorrhagia, sweats, flushes and tachycardia. More recently she had complained of much dyspnea and had had several fainting spells. She had had "bluish" hands for years. She continued her hard work. Examination showed auricular fibrillation (electrocardiographic tracings), moderate cyanosis, moderate hypertension and a heart only slightly enlarged (x ray). The clinical diagnosis was moderate cardiosclerosis, with superadded cardiac overstrain and climacteric hyperexcitability. Her physician gave her the routine quinidine capsules, and reported that the day on which she took the capsules there was slight nausea, later vomiting, slightly increased tachycardia, and slight throbbing in the head. The next morning the rhythm was normal, except for occasional extrasystoles. The systolic blood pressure was 100. The patient was comfortable, there was no dyspnea. The rhythm remained normal for several days, then fibrillation recurred. Quinidine was again advised. The heart action was again regularized. The rhythm remained regular at the last report, several months later.

It is a well known clinical observation that embolism as the mechanical result of breaking off vegetations of an infected valve, especially in mitral stenosis, is by no means infrequent. It can occur with or without auricular fibrillation. It is not always the result of tachycardia. Some years ago, for example, I saw a case of embolism of the popliteal artery in a patient with mitral stenosis, no tachycardia, no arrhythmia and no rheumatic exacerbation. In our patient, since the accident occurred within two days after the increased tachycardia from quinidine, it is only fair to assume that the more rapid and perhaps more violent heart action had some influence in causing the embolism.

Case V.—Mrs. H., seventy-four years old, had been an occasional sufferer from phlebitis of the legs for years. Her heart had been irregular for some time; the type of the irregularity as determined by the electrocardiogram was auricular fibrillation. She also suffered from occasional tachycardial attacks at night; this was usually accompanied by gastric distention. There was slight edema of the legs and mucous râles at both bases. She had been digitalized at various times during the preceding months; this generally controlled the tachycardia and to some extent lessened the edema and pulmonary signs. The orthodiascopic tracing showed an enlarged aorta and moderate left ventricular hypertrophy. The auscultatory signs were those of aortitis, the clinical diagnosis was aortitis and cardiosclerosis. After she had been thoroughly digitalized for the last time, she was given quinidine sulphate in five grain doses

according to the method I have already outlined. There were no specially alarming symptoms on the quinidine day. Altogether twenty grains had been given. The blood pressure was normal. The next morning the fibrillation had ceased entirely, the pulse and heart action were regular with the exception of occasional extrasystoles. The systolic blood pressure was 130, the diastolic 80. The patient felt perfectly comfortable in every way. Early in the evening the patient vomited and soon thereafter fainted. There were many single as well as grouped extrasystoles; for several minutes at a time there was typical coupled rhythm. After the first fainting attack the patient was taken with generalized convulsive seizures. She became markedly cyanotic. She was unconscious with widely dilated pupils. There were comparatively long periods of apnea. The urine contained a rather large quantity of albumin for the first time. There was no special change in the superficial or deep reflexes. The convulsive seizures though less violent than the initial attack, continued at irregular intervals during the night. During the whole of this time the patient was in coma. When I saw her the next morning her mentality was again perfectly normal. There was no dyspnea. The urine contained albumin and casts. Coupled rhythm was present. My impression was that she had entirely gotten over the serious phenomena of the night before, and that she would probably slowly recuperate. She simply complained of her tongue which she had bitten during her convulsive seizures. The patient died suddenly late in the evening. An autopsy could not be obtained.

The cause of the convulsive seizures and circulatory collapse may be attributable to two possible causes. First: The toxic quinidine effect on the cerebrum somewhat similar to what occasionally happens when overdoses of quinine are given. Second: The toxic effect of quinidine upon the heart muscle. In my opinion the latter was the cause of circulatory collapse, as well as of death. It seems to me that the convulsive seizures were probably caused by some secondary cerebrocirculatory disturbance, possibly a temporary thrombosis in the larger cerebral veins.

SUMMARY AND CONCLUSIONS

Eleven[1] cases of auricular fibrillation, properly digitalized, are reported in which quinidine sulphate was administered by the family physician at the patient's home.

Of these patients, three were male, eight female; six had valvular disease (mitral lesions), five myocardial disease (cardiosclerosis). Of the six with valvular disease, normal rhythm was permanently restored in two cases; in one, the rhythm remained normal for but two days; quinidine had no effect in regularizing the rhythm in the other three. Of the five cases with cardiosclerosis, the rhythm was permanently restored to the normal in three, in the other two there was temporary normal rhythm for a day or two.

Taking the entire eleven cases, and using the term permanent restoration in the restricted sense of the months that the patients were under observation, there was permanent restoration in five cases, there was temporary restoration for a day or two in three cases, and the drug had no effect on the fibrillation in the remaining three. In two of the eleven cases, quinidine was followed by untoward results. In one, (Case IX—mitral stenosis) there was embolism of the radial which may possibly be attributed to the drug. In the other (Case X—cardiosclerosis), quinidine was directly responsible for death from cerebral and cardiac complications. In both, the same accidents would in all probability have followed quinidine administration in a hospital, for there was nothing in the cardiac status following quinidine by which any complication could have been foretold. In fact, in the fatal case (Case X), only twenty grains of quinidine had been given. The complications occurred after normal rhythm was established. This case probably illustrates the fact that patients with venous thromboses of various kinds (varicose veins with phlebitis, etc.) are especially prone to develop thrombotic and other complications with quinidine (3). Hence in these patients quinidine, if used at all, should be administered with extreme circumspection and caution.

With a knowledge of its possible dangers, and with proper restriction of the type of cases for quinidine therapy, quinidine sulphate, properly administered in digitalized cases of auricular fibrillation may be given almost, if not quite, as safely in private practice, under the guidance of the family practitioner, as in the hospital.

One distinct advantage in hospital electrocardiographic control over treatment in private practice is the fact that quinidine sulphate occasionally has been shown to produce fleeting paroxysms or showers of ventricular extrasystoles. And it is known that such arrhythmia is occasionally, although rarely, a precursor of an almost immediately fatal arrhythmia, namely, ventricular fibrillation. It is not always possible to diagnose runs of ventricular extrasystoles by ordinary clinical methods; these are most apt to be mistaken for an irregularity produced by auricular fibrillation itself. Hence there is an advantage in taking frequent electrocardiograms in a hospital so as to fix the type of questionable arrhythmias; thus the occasional untoward runs of extrasystoles produced by quinidine may be discovered in time and the drug be immediately stopped before the irregularity develops into ventricular fibrillation and death.

Perhaps some time a method will be devised by which one may tell in advance which patients are apt to react unfavorably to quinidine sulphate in this regard, and thus even this possible complication be prevented.

[1]The cases not cited were omitted due to lack of space.

Repair of the Syphilitic Nose*

J. EASTMAN SHEEHAN, M.D., F.A.C.S., M.R.S.M., London

New York

Associate Surgeon and Lecturer to the International Clinic for Otorhinolaryngology and Faciomaxillary Surgery, St. Louis Hospital, Paris; Assistant Professor of Laryngology, New York Post-Graduate Medical School and Hospital.

INTRODUCTION

The most difficult work which the plastic surgeon is called upon to perform is the replacement or repair of the nose totally or partially destroyed by syphilis. The satisfactory results obtained in the treatment of such cases by the method which will be presently described and the apparent reasonableness of the method itself are, therefore, the justification for the submission of this paper. The experience from which the method has been developed consists of six years of work here and abroad, partly in operation as principal and partly in assistance upon and observation of the operations of H. D. Gillies, of Queens Hospital, Sidcup, England, one of the foremost plastic surgeons of the world.

The procedure is submitted with sufficient confidence in its effectiveness to warrant its recommendation. It differs from methods which have invariably proved unsuccessful in that it recognizes the necessity for providing and does provide the three elements of the nose, viz., epithelial lining, supporting structure and skin. Any attempt to restore nasal destruction which does not involve restoration in these three particulars will fail. Most, if not all, of the failures of the past can be ascribed to the attempt of the surgeon to make suffice for a nose a structure which lacked in some respect what is necessary for a nose.

It is not difficult to explain the cause of these failures. Surgeons have attempted to effect repair by implantations of cartilage or bone, injections of hydrocarbon and introductions of silver filigree, ivory and celluloid forms, ignoring entirely the necessity for an epithelial lining. There can be no other or greater benefit from such methods than an evanescent improvement in appearance. There is no life in the replacement, and as it retains the facies of the original destruction the eventual disfigurement is even more pronounced. A proper lining must be provided if permanent replacement is to be accomplished. Otherwise the bridge support will be no more an integral part of the structure than a walk-

the degrees of destruction. The treatment varies in direct ratio to the extent of such destruction distinguishing each class from the others.

THE FIRST CLASS

In the first, the intranasal structure is intact, there is some loss of mucous membrane replaced by scar tissue and partial destruction of the cartilaginous bridge. This type is less frequent than are the others. The deformity resembles that produced by the improper removal of the nasal septum, or by a septal abscess resulting in destruction of the upper portion of the cartilaginous bridge. The loss of mucous membrane is not extensive and is confined to the anterior superior quadrant. It is not necessary as a rule in this class of cases to provide a lining. All that need be done is to implant the proper amount of chondral cartilage correctly shapened to give the same support originally afforded by the cartilaginous septum. The method to be employed is described in *Laryngoscope*, September, 1922, and New York Medical Journal, January 26, 1921.

Fig. 13a.—Typical syphilitic disfigurement of the nose. Third class.

THE SECOND CLASS

In the second class, there is extensive destruction of the mucous membrane and usually of intranasal structure and of the bony and cartilaginous bridge. This is the type most frequently encountered. It is clearly differentiated from the first class by a loss of bony and cartilaginous framework with extensive replacements of mucous membrane by scar tissue. No successful result can be achieved in the treatment of cases of this class unless a lining is provided. The lost mucous membrane must be replaced with true skin and a supporting frame supplied. The proper lining is provided by grafting skin according to the Thiersch method, which, if successful, as is generally the case, will change the appearance of the nose to that which results from a simple depressed fracture. Later the appearance is improved by the implantation of chondral cartilage. The steps in the process will be presently described in detail.

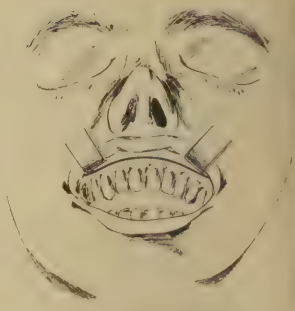

Fig. 2.—The incision.

Fig. 2 depicts this second class, the most common type of syphilitic deformity. The total loss of the frame has retracted the tip of the nose and its alæ. The vestibules are intact but adherent to the underlying bone and the shape of the pyriform apertures is consequently altered. To remedy the deformity the syphilitic contractures must be relieved and the nose restored to its normal shape and position. It is, therefore, necessary to separate the fibrotic attachments from the underlying bone. When the nose may be moved forward and backward at will, the operator will know that the fibrotic adhesions have been freed. There is then exposed a large area of raw surfaces

vhich must be covered with skin after the removal of scar tissue. With these preliminary explanations, ve are ready to proceed to a description of the operaion.

THE OPERATION

The patient is first referred to a dental surgeon killed in the art of making prosthesis appliances, vho will make a small removable cup splint to fit nto the upper teeth. If the mouth be edentulous, a pecial plate is made to which is attached the stanhion of the nasal appliance. To the centre of the plint there is attached an upright semiflexible piece f metal with three triangular wings. Its length will pproximate that of the raw area. (Figs. 4 and 5 re of an actual splint made by Jackson and Fraser, lental surgeons, Queens Hospital, Sidcup, England.) A cup shaped splint without the upright stanchion s fastened to the upper teeth, and an incision is made ne quarter of an inch above the gingival line exending from one canine fossa to the other. The inision is then extended laterally and upwards, seprating the syphilitic adhesions and freeing the alæ. The scalpel is then carried forward and upwards ver the lateral canthal and bridge areas of the nose, are being taken not to perforate the external skin. The nose may now be manipulated at will if the ndercutting has been thoroughly done. It should e retroverted as a glove is turned inside out and car tissue removed with delicate scissors until not vestige of such tissue remains.

SKIN GRAFTING THE RAW AREA

A mould of stent (dental modelling compound) s sterilized by boiling. A model of the raw area s made by inserting the sterile stent, made soft and liable by immersion in hot water, in the nasal cavity rough the buccal incision. Preparatory to so doing postnatal plug has been inserted in the nasal cavity nd the lower nasal chamber plugged with gauze ush with the pyriform aperture. The stent is thus revented from passing into the postnasal space nd the size and shape of the mould are controlled. The stent is pressed upward, then laterally and then orward to the tip until all the exposed raw areas re completely covered and an excess left to allow or subsequent contractions. The upright stanchion f the prosthesis appliance, heated in a spirits flame, then inserted upwards into the mould and screwed o the dental splint. The mould while warm must be anipulated to insure that the proper shape of the ose has been formed and that all the exposed raw areas are covered. Sterile ice water is sprayed through the nostrils causing the mould to set and it is then removed with the stanchion unscrewed from the splint. Difficulty may be experienced in removing the mould due to little protuberances adhering to the recesses of the intranasal chamber. Experience will disclose the location of these protuberances and they may be removed by melting with a hot septal separator.

Markings on the mould will show where the stent has actually come into contact with the raw areas. These markings are usually confined to the upper and lateral and upper tip part of the stent. It is the area thus identified which must be covered.

REMOVING THE THIERSCH GRAFT

The graft should, if possible, be cut in one large piece and thin in order that the whole mould may be covered and application to the nasal cavity facilitated. It is cut preferably from the right inner aspect of the thigh in a nonhairy area. The inner aspect of the arm may also be utilized. In cutting, deftness of hand, experience, the character of the assistance and the sharpness of the knife are the things that count. The graft is spread completely over the mould, raw side uppermost, care being taken to avoid wrinkles and slack. If the graft cannot be obtained in one piece, as is sometimes the case, the several pieces should be evenly spread over the mould with slight overlapping of the adjoining edges.

INSERTION OF THE GRAFT COVERED MOULD

The mould covered with skin and attached to the upright appliance is inserted in the nose per oral incision and secured to the base or splint attached to the teeth (see drawings). It should remain *in situ* for eight to ten days after which it should be removed and cleansed and the nasal cavity gently irrigated.

Inspection of the intranasal cavity now shows the formerly raw areas covered with an epithelial lining, grayish white in color. A mould of gutta percha is then made, patterned after the original one of stent and inserted into the nose to take the place of that removed. It is removed daily for cleansing purposes for a period of ten days to a fortnight, at the end of which time the graft, having become firmly adherent, a more permanent appliance (see drawing) is used to keep the nose in shape and prevent contractions. This appliance is removed and cleaned every few days. Its use is continued for

several months, when it is removed for good and the patient is ready for the implantation of chondral cartilage to serve as a bridge.

Chondral cartilage, taken from the right chest wall, is properly shapened and inserted between the newly made nasal epithelial lining and skin covering.

FINALLY

The mouth wound is then closed. If necessary the opposing surface may be freshened to insure closing. Sometimes it is necessary to do so as the wound area is purposely epithelized to prevent closure.

The graft described may be availed of as recognized surgical practice and if properly done will take in nine out of ten cases. In view of the nature of the deformity to be remedied, certainly the surgeon is at least justified in resorting to it.

THE THIRD CLASS—RHINOPLASTY

In the third class of syphilitic disfigurements there is destruction of the intranasal parts and total or partial loss of the skin covering, and rhinoplasty, more or less extensive, is the method of repair. The lining is obtained by swinging side skin flaps properly designed across the nose and sewing them together (see drawings).

The external covering is obtained from the forehead, scalp, upper chest, arm area or abdomen by the tube pedicle method of Gillies. The skin from the forehead best matches the normal nasal covering and the cosmetic result is best where it is used. The disadvantage is the resulting scar. A flap can be taken from the scalp and brought down to the nose. The hair roots may be epilated later by x ray.

An ingenious method of obtaining skin for the nasal covering is to tube the skin of the abdominal inguinal region, later attach the proximal end to the radial area of the wrist, finally sever the distal part of the abdominal tube and bring it up to the nose area (see drawings). After the flap is tubed the distal end as a rule is properly shaped and then taken up to complete the repair of the nose. Two to three weeks thereafter the pedicle is severed and returned to its original place. Later a cartilaginous bridge is implanted (see drawings).

In the repair of the syphilitic nose of this class there is undoubtedly a greater risk of gangrene occurring in a flap because the presence of syphilitic endarteritis interferes with the proper nourishment of the flap. Therefore, it is always advisable to have such cases cured of the disease before the repair is attempted.

Extensive Luetic Necrosis of the Frontal Bone Followed Sixteen Years Later by Cancer at the Edge of the Scar

DOUGLASS W. MONTGOMERY, M.D.,
San Francisco, Cal.

The bones and joints in early constitutional syphilis are often affected with pains tending to be most severe at night, and on this account called nocturnal, and also, because of their severity, as osteocopic or bone racking. These pains are partly due to the fever, and also partly to localized inflammations of the periosteum, extending along the bloodvessels into the Haversian canals. These localizations manifest themselves by pain and by circumscribed tenderness and swelling. They almost always recede and leave no trace. In the later stages of the disease localized inflammatory processes may also arise, usually affecting the very same bones as were involved in the early stages, but which, instead of receding, may lead to necrosis, sometimes extensive.

The bones most frequently affected by this grave malady are the anterior surface of the tibia, the bones of the skull, the clavicles, and less frequently the ribs and the fingers. In the old museums these skulls and tibiæ formed a prominent exhibit. They became less frequent on the introduction of iodide of potassium, and under the newer methods of treatment they have become still rarer.

CASE HISTORY

A woman, aged fifty years, consulted us on November 9, 1907, on account of a large ulcer of the forehead, as shown in the photograph. She said that it had appeared a year previously as a tumor, and that her medical attendant had curetted it. He probably had regarded it as an epithelioma. The wound had never healed, but had gone on steadily increasing in size. When I saw it there was a large ulcer with extensive denudation of bone, and with satellite ulcers about the main lesion. There was an erysipelatous inflammation of the nose and right eyelids, and, as particularly significant, an ulceration in the right nostril.

This was long before the days of the Wassermann reaction, but there could be no doubt of the diagnosis. Its rapidity, its multiplicity, its curvilinear steep borders, its rapid implication of the bone and the coexistent lesion in the nostril stamped it as being luetic.

In spite of all these factors, selfevident as they are when detailed here, I, on first seeing the patient, nearly made a mistake in the diagnosis. I had dismissed her as being unsuitable for any but surgical treatment, when fortunately it flashed across my mind that it must be syphilis, and I recalled her for further consideration. It was then that I became aware of the trouble in the nostril, and I then saw that the essential lesions were syphilitic, but blurred by pyogenic infection.

Her family history was also interesting. She had married thirty-two years previously and had been pregnant five times. The first pregnancy miscarried, which was attributed to carrying heavy weights. The second went to term and produced a fine child. The third pregnancy miscarried from some unknown cause. The fourth went to term and yielded a daughter. The fifth pregnancy miscarried, supposedly from riding horseback.

The diagnosis, as finally determined, was late luetic ulceration with streptococcic infection.

TREATMENT

Under mercury and potassium iodide improvement quickly set in, but progress was naturally slow, because of the large amount of dead bone and the extent of surface involved. Shortly after beginning treatment a large black hard crust was expelled from the right nostril. This process was accompanied by doughy swelling and redness of the skin, so that at one time it was feared that all of this side of the nose might melt away.

FIG. 1.—An ulcer with steep curvilinear borders and a most irregular floor, occupying a large part of the frontal region. In the midst of the ulcer there is a small dark area where the necrotic bone can be seen, showing through. The necrosis could be demonstrated in several other situations, but this one is the best, as seen in the photograph.

In August a large piece of the outer plate of the skull was removed. After this we tried, in order to hasten the healing, vitelline membrane of egg grafts, which now I suppose have only an historic interest. They failed.

After sixteen years, on on September 4, 1923, the patient consulted us again, and this time for a well marked epithelioma which had begun on the edge of the scar. And this time the danger lay in assuming too hastily that the epithelioma might be a recrudescence of syphilis. On close examination, however, the well known signs of epithelial infiltration were plainly visible. Furthermore, the picture was not now clouded, as it was formerly, by pyogenic infection.

A cicatrix is a weak tissue, and therefore, it is not surprising that a degenerative disease, as cancer is, should develop in it. In fact, it is known that in some situations, as on the tongue, cancers in the scars resulting from luetic infiltration are particularly likely to occur. The rest of the scar had remained solidly healed from the previous treatment.

Radium treatment for the epithelioma was begun on September 4, 1923, using for the most part a plaque containing twenty-five milligrams of radium, heavily screened with lead and rubber, and retained in place interruptedly for a total of sixteen hours. Under this treatment the epithelioma resolved perfectly.

323 GEARY STREET.

The Progress of Italian Syphilographers

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

The Italians have been doing good work in syphilis and an attempt will be made to review some of their most recent studies.

At a meeting of the Medical and Surgical Society of Pavia, Quattrini gave his results of ultramicroscopical examination of material obtained from puncture of the lymph nodes for the diagnosis of syphilis. This is a simple operation, and examination of the material withdrawn gave 88.24 per cent. positive results in patients who had remained untreated. Therefore, its value as a diagnostic measure is evident. I would also remark that Quattrini twice found the Spirocheta pallida in the lymph nodes of cases of frambesia, and then Monti has described spirochetæ obtained from the medullary substance of the lymph nodes and adventitia of the bloodvessels of the lymphatic parenchyma in some cases of infectious icterus. This method of diagnosis should be valuable in instances of latent syphilis.

A curious instance of primary pigmentary syphilide developing in large areas has been reported by Gravagna occurring in a syphilitic patient four months after an initial treatment of thirty injections of biniodide of mercury. On the dorsal aspect of both hands there was a large brownish black plaque which was limited by a straight line extending from the middle finger to the middle of the wrist. On the right hand, the thumb and index and middle fingers were involved, while on the left, the thumb and index were free from pigmentation. These pigment lesions disappeared in three weeks under daily injections of mercurial biniodide.

Pasini and Vigano have been using radiology for the diagnosis of bone syphilis. Employed in various cases of simple or ossifying periostitis, ostitis, and gummatous periostitis, they found that a special characteristic bone disease was an increase of the opacity of the bones, indicating a process of condensing ostitis, the reverse of the rarefying process present in tuberculosis. However, Martinotti, of Bologna, is inclined to hold a contrary opinion.

Cappelli has recorded the interesting case of a male, aged twenty-five, who contracted syphilis in 1915. He began suffering from cranial periostitis in 1916, and after recovery from this, cranial periostitis again developed in 1919, but this time there was ulceration and suppuration, especially on the right side of the skull. The necrosis extended down to the dura. He improved after a long series of novarsenobenzol injections and afterwards potassium iodide. Then later, he had an apoplectic ictus which involved the left side of the body, there being paresis followed by facial paralysis. He returned to the hospital in March, 1921, weak and emaciated, and with albuminuria. He died eleven days later.

At autopsy, the cranial lesions were remarkable on account of their extent; they involved all the bones of the vault of the skull and even the occipital bone. The disproportion between the limited lesions was interesting, likewise the long duration of the processes without subjective or objective disturbances of the nervous system, regardless of the participation of the dura in the gummatous process and the ensuing virulent septic infections. The parietals, frontal, and a portion of the occipital were necrosed and perforated, with areas of rarefaction and condensation of the bone.

Several instances of syphilitic reinfection have been observed of late in Italy. Minassian has met with three cases. The first patient was treated during the chancre before the Wassermann had become positive, the second when the Wassermann had become partially positive. Each was given a total of three grams fifty centigrams of neosalvarsan. The third patient was first treated late, during the secondary period after the roseola had developed, but treatment in this case was more energetic, consisting of a total of six grams of neosalvarsan, given in two series of injections with a short interval between them. In the two first cases, treatment was continued for three years with numerous series of calomel injections.

In the first patient, reinfection occurred twenty-eight months later; in the second patient, forty-eight months later, and in the third at the end of fifty-four months. In two cases the Wassermann was still negative during the first few days of the reinfection. In the third case a roseola followed the chancre. In two cases the new chancre occupied a different situation from the chancre of the first infection.

Piccardi, out of one thousand patients treated with novarsenobenzol, obtained twelve cures (1.2 per cent.) and supposes that this result may be obtained quite frequently if treatment be commenced at the onset of the secondary phase of the infection. If, as is generally admitted, the immunity against a second infection is dependent upon the persisting of the first, those cases in which a reinfection occurs with all the requisite characteristics, must of necessity demonstrate the possibility of a complete cure of the first syphilis controlled by clinical and serological investigation.

Generally it is admitted that an abortive cure may be obtained when the seroreaction is still negative before the fifteenth to the twentieth day from the first appearance of the chancre. Out of a total of twelve cases observed by Piccardi, seven realized this condition, and the remaining five dated from twenty to thirty-eight days from the onset of the primary sore. This observer also maintains that sterilization of the patient is possible during the entire second phase of incubation, and what is more, in one hundred cases of primary chancre he obtained a clinical cure with complete absence of any secondary manifestation during a lapse of time varying from six months to ten years, with a negative seroreaction, although the treatment was occasionally begun when the secondary symptoms had developed.

Of the twelve treated cases, four were given a

mixed treatment of novarsenobenzol and mercury; eight were treated exclusively with novarsenobenzol. Piccardi does not believe that large doses of arsenic are necessary; he employs from 0.45 to 0.60 centigrams as an average dose.

In the twelve cases of reinfection observed by Piccardi, this took place at intervals of two months to six years after the first syphilitic infection. In the cases where the interval between the cure of the first infection and reinfection was so very short, treatment of the first syphilis had been begun five days after the onset of the chancre.

Tommasi has also observed what seems unquestionably to have been an authentic instance of syphilitic reinfection. A male, at the age of fourteen years, developed chancres in the sulcus of the penis on the right side, followed by enlarged inguinal lymph nodes, erythema, headache, and general enlargement of the lymph nodes. This was in January, 1907, and treatment was begun February 27th, with twenty injections of sublimate in doses of 0.015 each. In June, 1907, the patient was given sixty injections of the same dose. Headache and pain in the bones recurred in June, 1908, and thirty sublimate injections were given. The patient was not treated again until the age of twenty-eight years.

For a long time the patient had had sexual intercourse with the same woman. On August 20th and September 28, 1920, he had connection with another woman who was examined by Tommasi, who found a positive seroreaction on December 10th, the man having contracted a chancre on the sulcus of the penis on the left side on December 1st. Spirochetæ were obtained from the lesion. At the same time there were enlargement of the left inguinal lymph nodes, erythema, headache, bone pain, and a positive seroreaction. At the end of December, mucous patches, with spirochetæ, appeared in the mouth, with generalized enlargement of the lymph nodes and emaciation. Unfortunately the patient had sexual connection with his former mistress on November 12th and 15th, namely, forty-five and fifty days after the infecting coitus. She contracted an endourethral chancre containing spirochetæ, and this was followed by erythema, facial paralysis, periostitis, etc. Therefore reinfection of the man cannot be doubted.

It is to be remarked that the treatment of the first syphilis in the man was mild, hence the early intense treatment recommended at present by most observers as essential for a radical cure, does not seem to hold. It is also evident that the first infection did not result in even a relative immunity for decreasing the virulence of the second infection, which was more severe than the first, both in the patient and the contaminated female.

Clinical Significance of the Negative Outcome of the Complement Fixation Test in Syphilis*

SIGMUND S. GREENBAUM, M.D.,
Philadelphia

Despite recent claims for precipitation tests the complement fixation test is at the present time the most commonly used laboratory procedure in the control, diagnosis and treatment of syphilis. So much value is placed on its positive outcome that few recall its limitations. So quickly do most of us consider syphilis excluded when the complement fixation reaction is reported negative on a single examination that we fail to remember the warnings of most serologists, that the interpretation of their results must rest to a large degree on the clinical picture, namely, the history, signs and symptoms—and on the therapeutic test.

With the advent of the Kolmer complement fixation test for syphilis (1) the positive outcome of the test, in this climate at least, may now be said always to indicate the presence of syphilis. That this is not always convincing proof that the nature of the condition under consideration is surely syphilitic must never be forgotten, since syphilitics may have other conditions besides syphilis and to which it often tends to predispose. The negative reaction, single test or provocative, does not by any means indicate the absence of syphilis. In this respect, even several negative reactions are not always conclusive of the absence of syphilis, as clinical cases herein reported show. It has already been pointed out, by Schamberg and Greenbaum (2), that even with the invaluable advance in the serological study of syphilis made by the Kolmer test, negative complement fixation reactions with this test still occur in the presence of known syphilis, indicating a lack of a hundred per cent. sensitiveness (as with any biological test and for the probable reason given below) despite its absolute specificity. The importance of recalling this possibility of negativity, particularly in tertiary syphilis, endosyphilis and parasyphilis, is selfevident and its cause of peculiar scientific interest.

THE NEGATIVE REACTION

From a practical viewpoint, the blood complement fixation reaction, in the presence of known syphilis, may be negative:

1. In the early days of the chancre.
2. In the late stages of syphilis.
   a. endosyphilis (latent or visceral).
   b. parasyphilis (tabes, paresis and neurosyphilis).
   c. tertiary (mucocutaneous) syphilis.
3. Temporarily.
   a. as the result of partial or irregular antisyphilitic treatment.
   b. after the ingestion of large amounts of alcohol (3).
   c. from causes not as yet understood (4).

*From the Research Institute of Cutaneous Medicine, Philadelphia, and the Department of Dermatology and Syphilology, Graduate School of Medicine, University of Pennsylvania, Clinic of Dr. Jay Frank Schamberg.

4. Permanently after efficient and sufficient treatment.
5. In congenital syphilis with active or latent lesions.

1. The production of complement fixing substances or reagin does not occur in the body, at least in detectable amount, as soon as the person contracts syphilis or even after the appearance of the primary lesion—this period of negativity varies from a few days after the chancre appears (always negative before) up to, in some instances, the appearance of the secondary manifestations when, with the new Kolmer test, it almost always, in our experience, becomes positive.

The cause of this period of negativity is generally regarded as being due to a lack of sufficient spirochetal activity with a resultant lack of body reaction and a consequent absence of reagin. Although we and others have already shown that, with the Kolmer test, this negative period is greatly reduced, still its presence in known primary syphilis has not been entirely eliminated for the reasons given. In the presence of a suspected chancre with dark field examination negative or this means not available, a "local complement fixation test" (5) on the fluid from the suspected lesion is in order and should this be negative, regularly repeated tests of the blood serum, the intervals not exceeding five days, are indicated. A lesion, suspected as being chancrous, must not under any circumstances be treated until the diagnosis is certain.

2. It is in the late stages of syphilis that considerable care must be taken in the interpretation of the negative outcome of a complement fixation reaction. Craig (6) estimates that with the Wassermann test, about thirty per cent. of parasyphilitic cases (tabes, paresis and acute neurosyphilis) about thirty per cent, of endosyphilitics (visceral, latent) and about thirteen per cent. of tertiary or mucocutaneous syphilitics will give negative blood reactions. These enormous percentages with the original Wassermann technic are significant and worthy of serious thought, particularly because of this, the innumerable modifications the test has undergone and the lack of a universal adoption of a standardized technic. The percentage of negativity with the Kolmer test has not been worked out in this clinic but from actual experience, although not entirely eliminated, they are considerably smaller in neurosyphilis and mucocutaneous syphilis. The following case report in point is cited:

Case.—G. M., female, black, aged twenty-three, was first seen March 19, 1923. The only facts of importance in her family and personal history was that of two pregnancies, one was a miscarriage and the other a stillbirth. The patient was generally in a poor condition and presented a widespread ulceration of two years' duration, involving the labia minora (which had been almost completely destroyed), the labia majora, the lower vaginal tract (anterior and posterior walls). The edges of the ulceration were firm and markedly sclerosed; the urethral orifice was partially occluded and later, as healing occurred, completely necessitating operative dilatation. It was painful and tender (probably due to an associated gonorrheal vaginitis) and covered with a thick mucopurulent material probably of gonorrheal origin also.

Twenty-four complement fixation tests were performed during a period of four months: the reaction was negative in the first seventeen tests, weakly positive on two and strongly positive on one later occasion. Under regular intravenous neoarsphenamine treatment, gradual improvement both generally and locally took place, until at the present writing the lesion is completely healed.

Klauder and Kolmer (7) and others have shown that the specific complement fixing substances have both a local and hematogenous origin. As these authors demonstrated its local origin in primary lesions only, before the blood reaction became positive, it would appear safe to assume that reagin originates at and probably only at the site of spirochetal activity (cellular theory). If this be so, as many believe and as studies on various cutaneous ulcerations appears to confirm (8), the clinical case cited above would be specially indicative of this. Positive local complement fixation reactions on fluid obtained from syphilitic tertiary ulcerations in patients with a negative blood reaction have not as yet been reported. In this instance three tests conducted on the fluid obtained from the ulcerated areas and at times when the blood reaction was negative gave anticomplementary reactions. Once when the blood reaction was weakly positive the local reaction was likewise weakly positive but quantitatively to a lesser degree. It is possible that reagin produced at the site of spirochetic activity enters the blood; but as in our patient, particularly in instances where considerable sclerosis occurs, in a way walling off the condition, little or no reagin gains access to the general circulation and the blood reaction is as a result weakly positive or completely negative.

Positivity in the early stages is reduced as nature tends to wall off the irritant and the products of spirochetic activity. Does the blood negativity that some acquired chronic syphilitics and a greater unknown percentage of congenital chronic syphilitics develop indicate a similar process? Rothschild (9). Beltran (9), and Kolmer (9) have observed chronic leg ulcers, of syphilitic nature clinically, with dense surrounding sclerosis, negative or weakly positive complement fixation reactions yet healing perfectly under treatment. Parasyphilitics and endosyphilitics easily conform to the same theory. In this connection, it is worth recalling that about ten per cent. (10) of parasyphilitics present negative blood complement fixation reactions but with positive spinal fluid reactions. Such cases particularly point to the local origin of reagin, that is in the spinal cord and brain, the site of spirochetic activity, since spinal fluid under these circumstances corresponds, in part at least, to the serous fluid from primary and tertiary lesions. When the blood complement fixation test is positive in such cases, it is because there are open lesions elsewhere in the body.

Although mucocutaneous and parasyphilitic lesions can usually be diagnosed clinically, offsetting the laboratory report of a negative complement fixation reaction, it is much more difficult clinically to diagnose endosyphilis or visceral syphilis under the same circumstances. It is definitely known that spirochetes—active?—may exist in chronic syphilitics with visceral lesions and blood negativity (Warthin). The recent reports on the serological relapses of syphilitics after seven years of negativity would

appear to confirm this, if the present conception of the meaning of a positive complement fixation reaction in syphilis is maintained.

3. The temporary reduction of a positive complement fixation reaction in partially treated syphilitics is well known to syphilographers (Cases II to VIII, inclusive). The commonest and most important from the practitioner's point of view is that occurring shortly after the institution of treatment, particularly in chronic syphilitics. For this reason and for another given below, the administration of but a few doses of one of the arsenobenzenes cannot be too strongly condemned. If arsenobenzenes are to be used in the treatment of a syphilitic then maximum totals for maximum effect should be given. Smaller amounts at irregular intervals tend to the production of arsenic fast spirochetes. In any case treatment should be continued with mercury and preferably bismuth.

The corollary to the above is the importance of never treating a genital lesion of suspicious syphilitic nature until the diagnosis is certain. The arsenobenzenes, administered to patients in the primary stage but with, as yet, negative blood fixation reactions, will prevent positivity. In sufficient doses this is certain; in insufficient doses they but retard it. Non-secondarily infected primary lesions usually heal spontaneously; most secondarily infected ones do not, unless the spirochetic factor is removed and the local tissue nutrition thus improved. A physician suspects but is not certain of the diagnosis; the complement fixation reaction is as yet negative; he administers two or three doses of one of the arsenobenzenes; the fixation reaction is still negative (naturally or because the drug has retarded the appearance of reagin) and the physician concludes that he was dealing with some other condition. Because of a lack of a correct diagnosis and the resultant insufficient treatment the subsequent development of a positive reaction goes undetected for years. This undoubtedly explains, in part at least, the reason for the large increase of chronic syphilitics.

An examination of the reports of Cases II to VIII, inclusive, is interesting. It will be noted that there is no relation between the time of development of negativity and the relapse to positivity to the time when treatment was first instituted. This does not occur irrespective of the stage of the infection as has been noted above. This tendency to negativity with later relapse to positivity is much rarer in systematically treated primary and secondary syphilitics; it is common in chronic syphilitics. In these latter it may occur after the first or not until the seventh or eighth injection. They may have relapsed sooner as but weekly tests were made. The duration of the negative phase as based on weekly tests and under neoarsphenamine treatment alone, varies from one to seven or more weeks.

From the above, it may be seen how false the sense of security a single complement fixation test, taken at an unfortunate time, often gives. The too frequent making of blood tests during the course of treatment of a syphilitic is to be guarded against. Syphilitics require a maximum amount of treatment once the complement fixation reaction has become positive. A fairly definite rule, adopted by most syphilographers, is to count no syphilitic proba-

bly cured unless his blood (and at least one spinal fluid taken at the same time) complement fixation reaction is negative at least two years after the original positive finding.

4. In congenital syphilis, although the positive outcome of the complement fixation test is a sure sign of syphilis, the negative reaction by no means excludes the presence of that disease. Negativity, in the presence of known congenital syphilis, is especially common. This fact is important to remember as not infrequently it gives a false sense of security, particularly to physicians who examine children to be placed in homes. It is also well always to warn parents themselves syphilitic, that negativity in their offspring, is a sign of variable value.

Diagnosis and Treatment of Syphilitic Exophthalmic Goitre

ERNEST SCHULMANN, M.D.,
Lyons, France

It is not always an easy matter to make an absolutely sure diagnosis of a syndrome when one has not the proof represented by the causal factor. Up to the present time I am unaware of any researches undertaken to discover the treponema pallida in miscroscopic sections of the thyroid gland. Given the great sensitiveness of the syphilitic virus to mercurial or arsenical treatment, such researches would undoubtedly be failures, because as soon as these substances are introduced into the organism the spirocheta tends to disappear. On the other hand, as I shall attempt to show, the therapeutic results obtained in cases of syphilitic exophthalmic goitre are in general quite favorable, so that the case is not apt to come into the surgeon's hands. I am firmly convinced that if a bit of thyroid were removed for microscopical examination in a confirmed case of syphilitic Basedow's disease the spirocheta would be detected, because this organism has a predilection for glandular parenchyma.

The action of antisyphilitic treatment is one of the best proofs we possess of the etiological cause of the affection, although frequently one will be dealing with old sclerous lesions so that the treatment may be doubtful in some subjects or variable in results according to the degree of activity locally presented by the treponema. In a general way, however, those cases where more or less relative failure ensues are rare as compared with the numerous unquestionably favorable results obtained.

In passing, I would mention the diagnostic importance of Wassermann's reaction, which should never be neglected in cases of syphilis, even when of long standing, as well as reactivation of this reaction. One must likewise take into serious consideration the search for the varied stigmata of hereditary syphilis in the patient's antecedents. When dealing with instances of familial exophthalmic goitre the physician should invariably be suspicious of the socalled neuropathic heredity and direct his clinical investigation to more real data.

Morbid associations in many cases should also be a warning, although often a rather late one. For example, a case of confirmed locomotor ataxia associated with Basedow's syndrome will give therapeutic results evidently mediocre. In a remarkable article on the differential diagnosis of morbus Basedowii, Stern (1) distinguishes typical exophthalmic goitre from the basedoid type. He maintains that the former is the true exophthalmic goitre in the antecedents of which one never finds infectious diseases such as typhoid, syphilis or rheumatism, diseases upon which the latter often depends.

What should be thought of the larvate states which Stern calls basedoid, met with so commonly in practice? May it not be assumed that an exophthalmic goitre developing from the onset startlingly evident symptoms represents a rapid involvement of the thyroid gland, by an infectious process electing this organ and neglecting all other localization? Thus could clinically be explained the intensity of the onset and absence of other symptoms. On the contrary, syphilis is more often characterized by a slowly progressive invasion; the spirocheta only progressively vitiates the thyroid parenchyma, and the glandular secretion thus being slowly disturbed, it follows that the clinical physiognomy becomes outlined discreetly.

Another question is: When do these larvate forms begin and at what time in the process can the term exophthalmic goitre be applied? It is not my intention to enter into the discussion of this highly interesting question, which would carry me far beyond the limits of this short paper. I would merely

say that Joffroy, as far back as 1888, presented seven cases of tabes with tachycardia before the *Société médicale des Hôpitaux de Paris,* and showed that six of them offered a more or less marked protrusion of the eyes, while two had hypertrophy of the thyroid and tremor. Joffroy thought that four of the seven cases presented Basedow's disease and he concluded that locomotor ataxia might give rise to tachycardia and also perhaps to a slight degree of exophthalmos either on account of some central lesion, a change in the peripheral nerves or by some simple functional disturbance.

CLINICAL STUDY OF A FAMILY

The clinical study of a family, of which I possess detailed notes, is of the greatest interest, but I will merely give a brief summary of each of the eleven children composing it.

Children Nos. 1 and 2 died in early life. Child No. 3, Lucy, died at the age of three years of an affection of the spinal cord. No. 4, Léon, died at fifty years. A confirmed tabetic, he lost his sight and appeared to have had an exophthalmos. He also had ulcers on the legs. No. 5, Victor, is aged fifty years. He never contracted any venereal disease. At the age of forty-two he was suddenly seized by retention of urine, which led to the discovery of tabes. At present ataxia is marked, Argyll-Robertson sign present, absence of tendon reflexes, no goitre, but the eyes are brilliant and bulge slightly; heart beats eighty-five to the minute. No. 6, Martha, was not examined.

No. 7, Louis, is aged thirty-eight years. He had never been ill, did his military service, was not alcoholic. He had noticed a tendency to tremor; vasomotor reactions were sharp and he blushed easily and sweated abundantly. He was very nervous and irritable, had slight exophthalmos, eyes were brilliant, there was slight tachycardia, pulse ninety beats a minute. Tremor varied but was always distinct, including tongue. There was no goitre or dental deformity; a patch of leucoplasia on mucous surface of right cheek. No. 8, Helen, was aged thirty-six years. During the last eighteen months distinct signs of Basedow's sydrome had progressively developed. There was a large goitre, more evident on the right side; tachycardia, 120 beats a minute. She complained of nocturnal palpitation; no cardiac lesion. Exophthalmos; Moebius, von Graef and Stellwag's signs positive. She was unmarried; menses regular; Wassermann reaction positive in blood.

No. 9, Louise, aged thirty-three years, married; one child aged seven years, in good health. Patient had been nervous since the age of three years. Slight exophthalmos; eyes brilliant; very slight tremor. Pulse rate, one hundred a minute. Some cardiac erethism; auscultation revealed a double second sound apparently not due to mitral stenosis. No dental stigmata; slight deafness on right side. Wassermann was positive in blood.

No. 10, Marguerite, aged thirty-one years, married, no miscarriages, three healthy children. She had never been ill until a characteristic Basedow syndrome developed at twenty-six years. There was a voluminous goitre, especially on the left side; circumference of neck thirty-six centimetres; neck increased in size during menses and from emotional causes. There were no disturbances of the voice. There was a systolic murmur, constant tachycardia, pulse 110 beats a minute, regular; oculocardiac reflex negative. Severe exophthalmos; von Graef, Moebius and Stellwag's signs present. No periocular pigmentation, paralysis, or nystagmus; eyes brilliant; very rapid tremor, especially of limbs during movement. Patient was very nervous, suffered from frequent heat flushes alternating with sweating attacks. Tendon and cutaneous reflexes were normal; Romberg and Argyll-Robertson absent. There was marked dental stigmata with retrognathism. Wassermann was positive in blood.

No. 11, Fernande, aged twenty-six years, unmarried, was always nervous but never ill. Menses regular, no sweating, no goitre, no enlargement of neck. Distinct but mild exophthalmos, eyes brilliant; tachycardia, 130 beats a minute. Blood pressure with Pachon, maximum 17, minimum 10; oculocardiac reflex indifferent; tremor, especially of hands. There was no dental deformity, but marked retrognathism. Patch of leucoplasia on left side; Argyll-Robertson negative; Wassermann positive in blood.

Victor, the fifth child of the family, and a confirmed tabetic, presented an insignificant tachycardia and a slight exophthalmos and it is a question whether or not these extremely larvate symptoms of Basedow's disease should be attributed to the tabes, when among the patient's collaterals five brothers and sisters presented unquestionable signs of the syndrome. Therefore, the question of the syphilitic origin of the exophthalmic goitre being left aside, it is of interest to be able to estimate the degree of defectiveness of the thyroid secretion by humoral reactions, since in reality we are dealing with a glandular disturbance. Hence a few words in respect to recent research work undertaken in this direction may not be out of place.

REID HUNT'S ACETONITRILE TEST

Hunt studied the antitoxic action of the thyroid gland by the use of acetonitrile, a compound whose toxicity is due to the giving off of free hydrocyanic acid. Experiments made with white mice showed that animals fed on thyroid preparations offered an increased resistance to acetonitrile and that in this resistance the potency of the thyroid is proportional to the amount of iodine it contains. If, instead of feeding mice with thyroid preparations they are given dried blood, obtained from an exophthalmic goitre patient, for ten days, a remarkable resistance of the animals to injections of acetonitrile ensues. A dose of thirty-two milligrams will kill the control animals, whereas forty-eight milligrams are easily supported by the mice fed on the dried blood.

Several observers have repeated these experiments, among them Trendelenburg, Herbert, Lussky, Carlson and Woelfel, and Ghedini, with results more or less in accord with those of Hunt.

Before the war I undertook, in collaboration with Garnier, to verify these curious experiments. We employed mice fed on thyroid extract and another lot fed on blood from a case of Basedow's disease. The results seemed fully to confirm Hunt's results,

but we were unable to carry on our work sufficiently to regard our findings as absolutely conclusive.

Fraenkel has shown that a marked hyperadrenalinemia is found in the circulating blood in patients with Basedow's disease. In his experiments, the amount of adrenaline was measured by comparative observation of the force and frequency of contraction of a bit of uterine tissue from a rabbit, in an isolated state and in serum.

This experiment may be carried out by other procedures. Moltzer and Ehrmann studied the production of adrenaline mydriasis in frogs, while Cameron believes the best method is to determine the effect of adrenaline on the blood pressure in rabbits previously atropinized. Hoskins devised a technic based on the principle that adrenaline stops the movements of an isolated segment of intestine of a rabbit when immersed in Ringer's solution.

All these biological procedures for the research of the blood adrenaline are interesting, but they are very delicate to carry out. Falta, who believes there exists a Basedow adrenalinemia and likewise admits that intravenous injections of thyroid extract produce a secretion of adrenaline, also thinks that the latter phenomenon is met with in numerous clinical conditions, and Cannon especially has insisted particularly upon its occurrence in emotive states.

ABDERHALDEN'S DIALYSIS TEST

This has given doubtful results in the hands of Lampe and Fuchs and this complex method has practically been discarded.

Roseo, repeating the initial researches of Papazolu and of Marinesco, attempted a study of the deviation of the complement in Basedow's disease, using an alcoholic extract of a Basedow goitre obtained by thyroidectomy as an antigen. Their results are encouraging and worthy of further examination and study.

Lastly, René Porak has resorted to the use of the action of hypophyseal extracts on the cardiovascular apparatus and glycosuria in the diagnosis of exophthalmic goitre. It appeared to this investigator that extracts of the hypophysis constantly slowed the pulse rate in Basedow's disease, a phenomenon invariably absent in all other forms of tachycardia, while the hypophyseal glycosuria is occasionally increased. These experiments are of the highest interest and will certainly, if continued, give further important results.

Therefore, it is possible that in the near future one may be able to appreciate by humoral reactions the disturbance produced by the secretions of a diseased thyroid gland. From the purely clinical viewpoint, the diagnosis of the classical Basedow syndrome will always be easy, but in larvate cases the diagnosis may remain a matter of doubt and it is in these circumstances that the physician should think of hereditary syphilitic dystrophic myopia—a rare condition it is true, a few cases of which have recently been reported by Prof. Gaucher.

For years the profession has attributed an important diagnostic value to antisyphilitic treatment in suspicious cases where the first examination does not confirm the fact that lues is not the certain cause of the morbid process presented by the patient, and although we now have the Wassermann reaction, whose value is unquestioned, nevertheless it has not dethroned the older test. In the somewhat complex question of syphilitic exophthalmic goitre, the quite remarkable action of antiluetic treatment in the majority of cases fully justifies the etiological classification that I propose. The results obtained are variable, but in a general way satisfactory, as the table of cases treated shows. (See table of therapeutic results.)

Recent publications, especially the researches of Roussy and Clunet, reveal the fact that Basedow's syndrome follows upon a thyroiditis which itself has created a more or less marked glandular hyperplasia. In practice the physician will meet with varied clinical examples; sometimes the case is one of early syphilis in which exophthalmic goitre makes its appearance; in other patients the syndrome has existed for years in a more or less larvate form in cases of long standing syphilis or in hereditary syphilis. In still other instances one is dealing with a common goitre which becomes basedowified from the action of the spirocheta pallida. Hence it becomes apparent that specific treatment will act differently in these various circumstances. When the lesion is still in activity and vitiation of the thyroid secretion has not become formally established and the causal agent—the spirocheta pallida—still intervenes on its own account, one should rightly expect positive results from treatment if this be carried out vigorously and thoroughly. But when the lesion is of long standing, where fibrous tissue has carefully walled in foci of endocrine hyperplasia, the secretion becomes more or less permanently changed. In these circumstances treatment still is valuable, as will be seen by consulting the table, but amelioration will generally be in inverse ratio to the chronicity of the glandular involvement.

THERAPY

The small number of exophthalmic goitres so far treated is not enough for one to appreciate the value of antisyphilitic treatment by modern methods.

In eleven cases mercurial treatment was resorted to; in five, mercury benzoate was the agent used; in two cases mercury biniodide was used, and in the remaining four cases the compound used is not mentioned. In three other cases neosalvarsan or novarsenobenzol was used. In the remaining cases iodides were given alone or in combination with mercury.

The latter cases are particularly remarkable. It is a well known fact, upon which Penzold has rightly insisted, that, in general, Basedow patients very badly support iodine or its compounds. Syphilitic Basedow cases, on the contrary, derive excellent results from this treatment and in Zelener's patient (Case XV in table) for example, a single iodine treatment resulted in an absolute recovery.

The value of specific medication in syphilitic exophthalmic goitre appears to be exceptionally evident and in many cases one need only resort to it without any other therapeutic measures being brought into play. These results are in accord with the recent researches of Roussy who says: "Only those treatments directed to the principal cause . . . would seem to be efficacious."

Besides the mercury, arsenical and iodine pre-

parations, certain general therapeutic procedures directed against the changed thyroid secretion may be tried. I would merely mention sodium salicylate recommended by Chibret and quinine sulphate as advised by Lancereaux and Paulesco. It is an undoubted fact that these two drugs act as antiinfectious agents and as such, as Roussy has pointed out, are capable of exercising a marked action at the onset of the process, that is to say, in the phase where Basedow's disease is still a thyroiditis.

One will, however, be more inclined to resort to hematoserotherapy which was in vogue a few years ago, among them being antithyroid chemotherapy, devised by Ballet and Enriquez, which by the use of hematoethyroidine diminishes the untoward effects of hyperthyroidization by introducing into the organism a certain amount of neutralizing toxic substance which these observers maintain relieves the insufficiency of the toxic substance to be neutralized.

Thyrotoxic serotherapy is based on the principle of cytotoxic sera. An animal subjected to repeated injections of thyroid gland will form antibodies in its serum susceptible of hindering the functions of the thyroid secretions. This treatment has given brilliant results in the hands of Rogers and Beebee, but its technic is delicate.

In patients presenting a syndrome where an excessive and disturbed function of an endocrine gland is incriminated, one may hope that a decrease of the clinical symptoms may ensue after ischemic atrophy or partial excision of the parenchyma. But regardless of the brilliant results of surgical treatment of exophthalmic goitre I maintain that medical treatment in the syphilitic form of the affection should prevail.

THERAPEUTIC RESULTS OBTAINED BY ANTISYPHILITIC TREATMENT

Silver Salvarsan in the Treatment of Syphilis

*A Comparison with Neosalvarsan**

WILLIS A. WHITMAN, M.D.,

Columbus, Ohio

"Silver salvarsan was first made by Ehrlich, but was not introduced into the therapy of syphilis until early in 1918, when Kolle, the successor to Ehrlich, announced the clinical experiences with this product from the George Speyer House. Kolle and Ritz found that silver and its salts exert a decided antisyphilitic action on experimental syphilis in rabbits. The increased antiluetic action of silver salvarsan is explained by the synergistic action of silver and salvarsan. Silver salvarsan was first manufactured by Farbwerke, vorm, Meister, Lucius and Bruening, the original producers of salvarsan and neosalvarsan. . . . The consensus seems to be that silver salvarsan is a decided forward step in the chemo therapy of syphilis. It is less toxic than salvarsan to animals and its trypanocidal activity is approximately twice that of salvarsan and three times that of neosalvarsan. The official toxicity test of silver salvarsan requires a twenty per cent. higher tolerated dose than that of salvarsan" (1).

"Silver salvarsan is a brownish black powder, readily soluble in room temperature water." It is "the sodium salt of silver diaminodihydroxyarsenobenzene (the exact molecular formula has not yet been established). It contains approximately twenty per cent. of arsenic and approximately fifteen per cent. of silver" (2).

The solvent used, in the treatment of the cases reported, was .4 sodium chloride solution using forty c. c. of solution to .1 fram of silver salvarsan; .1 gram was given for the initial dose, .2 gram for all other doses except the last, when .3 gram was given.

All patients treated were adult males, either white or black, 162 men being treated. Treatments are given weekly. Approximately four minutes' time is allowed for the administration of the drug. Preceding the administration of the silver salvarsan, three treatments are given, each consisting of one gr. of mercury salicylate, intramuscularly, and, at the same time thirty-five gr. potassium iodide and 0.3 gr. bichloride of mercury are given, orally. After

*Report of 162 cases treated at the Ohio State Penitentiary.

the third treatment of mercury salicylate the administration of the silver salvarsan is begun, with one treatment weekly. During the time the patient is under silver salvarsan treatment, he is, also, kept on the mercury salicylate, injection weekly, and these injections follow the close of the administration of the silver salvarsan, until fifteen treatments, in all, of mercury salicylate have been administered.

One month following the completion of all treatment blood is drawn for Wassermann test to determine the result of the treatments. No routine spinal fluid examination was made for the determination of the progress of the treatments; blood examination alone being used as a check.

In all cases where additional treatment is administered, three additional injections of the silver salvarsan are administered immediately following the close of the mercury salicylate, without the mercury salicylate. These injections are given at four day intervals, except in some cases where the entire course of treatment is repeated.

In all cases reported where neosalvarsan was used the same technic was observed, as regards the administration, with the exception that .3 gm. was used as the initial dose, .6 gm. following initial dose until the last treatment, when .75 gm. was administered.

In the fifty-five cases treated with neosalvarsan, fifty-four patients had tertiary syphilis, while only one patient had primary syphilis.

NEOSALVARSAN TREATMENTS

Cases treated	55	100.0 per cent.
Cases becoming negative	19	34.5 per cent.
Cases remaining strongly positive	12	21.8 per cent.
Cases responding to treatment	23	41.8 per cent.
Cases treated, but no check	1	1.9 per cent.

In these cases twenty-five patients admitted chancre and twenty-one admitted gonorrhea; while twenty-seven denied chancre and thirty-four denied gonorrhea. Three patients could give no history of infection. Of the fifty-five cases treated with silver salvarsan, all cases were tertiary syphilis.

SILVER SALVARSAN TREATMENTS

Cases treated	55	100.0 per cent.
Cases becoming negative	24	43.5 per cent.
Cases remaining strongly positive	13	23.6 per cent.
Cases responding to treatment	18	32.9 per cent.

In these cases eighteen patients admitted chancre and thirty-three admitted gonorrhea; while thirty-four denied chancre and twenty-one denied gonorrhea. One patient could give no history of infection.

RESULTS COMPARED

A comparison of the results obtained in the use of silver salvarsan, as compared with the results obtained in the use of neosalvarsan, is as follows:

Negative with the use of silver salvarsan	43.5 per cent.
Negative with the use of neosalvarsan	34.5 per cent.
Responding to treatment—silver salvarsan	32.9 per cent.
Responding to treatment—neosalvarsan	34.1 per cent.
Remaining strongly positive—silver salvarsan	23.6 per cent.
Remaining strongly positive—neosalvarsan	21.8 per cent.

Fifty-two patients were given additional silver salvarsan, some received three extra injections, while others received two or more regular courses (3) of treatment. Forty-seven of these patients had tertiary syphilis, while five had primary syphilis. Of the five primary cases, two became negative, two responded to treatment and the other one remained strongly positive.

THREE OR MORE EXTRA INJECTIONS

Cases treated	52	100.00 per cent.
Cases becoming negative	26	50.00 per cent.
Cases remaining strongly positive	7	13.46 per cent.
Cases responding to treatment	19	36.54 per cent.

In these cases thirty patients admitted chancre and thirty admitted gonorrhea, while fifteen denied chancre and twenty-two denied gonorrhea. Eight patients could give no history of infection.

The response to treatment was much greater where additional treatments were given, this being shown by fifty per cent. becoming negative and 36.54 per cent. responding to treatment, not to negative, a total of 86.54 per cent. responding.

A comparison of the results obtained in the use of three or more extra injections with the results obtained in the use of one regular course of silver salvarsan is as follows:

Negative with regular course	43.5 per cent.
Negative with three or more additional injections	50.00 per cent.
Responding to treatment (regular course)	32.9 per cent.
Responding to treatment (three or more additional injections)	36.54 per cent.
Remaining strongly positive (regular course)	23.6 per cent.
Remaining strongly positive (three or more additional injections)	13.45 per cent.

Many of the patients who received extra injections were men whose reactions remained strongly positive following the first course of treatment. Hence, the higher percentage obtained when the extra treatments were given is made more strikingly apparent. Many of the patients given additional treatments were not as responsive to treatment as others. Frequent reactions were observed during the treatment of the men given neosalvarsan with occasional dermatitis showing, and frequently necessitating the hospitalization of the patient. During the administration of silver salvarsan there was rarely ever a reaction necessitating the hospitalization of the patient, and no dermatoses.

My observations were that the reactions following the use of silver salvarsan were negligible as compared with those following treatment with neosalvarsan.

In all cases the Wassermann test (4) was repeated after thirty days of completion of treatment, and in many cases was repeated again eighteen months later, and the final test was the one used in the report of cases.

CONCLUSIONS

1. It has been demonstrated to my satisfaction that the therapeutic value of silver salvarsan is greater than that of neosalvarsan.

2. The toxic effects exhibited by silver salvarsan have been much less than those exhibited by neosalvarsan. This fact makes the use of silver salvarsan more desirable from the point of view of both the patient and the physician.

3. The use of additional treatment is indicated from the viewpoint of end results.

3. Regular course being seven intravenous injections of either neosalvarsan or silver salvarsan and fifteen injections, intramuscularly, of one grain each, mercury salicylate.
4. All Wassermann examinations were made by the State Department of Health Laboratories.

Oculomotor Paralysis of Syphilitic Origin

Treated with Mercury and Iodides

CHARLES ROSENBAUM, M. D.
New York

Case.—H. C., forty years old, male, was first seen by me last November. He complained of inability to open his right eye for the past three days. Prior to the day of his trouble he had gone to bed perfectly well and awakened with his right eye closed. His past history was interesting to the extent that he had been married twice and in the interval between marriages admitted the possibility of specific infection. He had two children by his first wife and none by his second. Neither of his wives had had any miscarriages.

When the ptotic right eye was raised the pupil was seen to be completely dilated. It was unresponsive to light or accommodation. Vision was O.D. 20/50, O.S. 20/30. The raising of the upper eyelid caused diplopia. A false image was projected to the left of the real image. The false image was binocular as it disappeared on exclusion of either eye.

The patient could abduct the eye, but could not adduct, elevate, or depress the right eye. The left eye was unimpaired, being freely movable in all directions. There was a paralysis of all the muscles supplied by the oculomotor nerve of the right side, both intrinsic and extrinsic. The external rectus and the superior oblique remained active.

Both fundus oculi were negative, Wassermann positive. The Wassermann of the second wife was negative. There was no neurological symptoms, such as Romberg, and loss of patella reflex.

After six weeks of antisyphilitic treatment, consisting of weekly injections of salicylate of mercury and forty-five grains of potassium iodide daily, the patient recovered the use of the oculomotor nerve. He could raise the levator, he could abduct, elevate, depress or rotate the eye, and the pupil responded to light and accommodation.

The rapid response to treatment in this case shows that mercury and iodides are effective without arsphenamine.

The differential diagnosis from other causes of oculomotor paralysis is quite evident: the history, the Wassermann reaction, and the therapeutic result.

Observations on the Bismuth Therapy of Syphilis with the Oxybenzoic Acid Compound

H. EDWARD AHLSWEDE, M.D.,
WERNER BUSCH, M.D., D.Nat.Sc.,
Hamburg, Germany

A general review of the progress made within the last few years in the treatment of syphilis with bismuth compounds shows that some definite conclusions may be drawn concerning the particular indications and the method of administration. As with the arsphenamines the immunatory and spirocheticidal effects in bismuth compounds run parallel. Both of these, however, and particularly the former, vary so considerably in the individual patient that no hard and fast rules can be laid down. Each case will therefore require individual handling.

Primary syphilis may be treated effectively with bismuth compounds alone, though this should not be made a general rule and is in fact strictly indicated only wherever for some reason arsphenamine medication has to be avoided. Thus we have treated a seronegative primary case (the patient had a serious vitium cordis) exclusively with the oxybenzoic acid compound of bismuth (bismogenol). Fifteen injections of one c. c. in two to three day intervals effected disappearance of the induration in ten days while all secondary symptoms were prevented except a positive fluctuation of the Wassermann and Sachs-Georgi reactions. This positive fluctuation appeared after the first few days of treatment and would in all probability have been provoked by arsphenamine also. At the end of the course however both reactions were completely negative and remained negative.

As far as we can judge, from our clinical results at the present stage, bismuth compounds seem to promise most in the treatment of cerebral syphilis and incipient tabes. Mueller (1) has traced ample quantities of bismuth in the spinal fluid. He also observed a decrease of the pleocytosis and of the first phase, as well as a distinctly beneficial influence in syphilis of the central nervous system. Our clinical experiences correspond to these observations in a large number of cases of cerebral syphilis which we treated with the oxybenzoic acid compound of bismuth.

A further indication for bismuth therapy is given by its prophylactic value. Levaditi and Sazerac in a series of animal experiments observed that bismuth compounds either in ointment form or by intramuscular injection guarantee a protection against infection as long as three hours after the invasion of the spirochetæ. Bismuth resistant cases have been ob-

served occasionally. It appears though that the resistance is less directed against the bismuth as such but rather to its particular compound and vehicle. Logically a change of the compound is indicated here. One will rarely be forced to give up bismuth medication entirely as may happen with arsphenamine in a case of idiosyncrasy.

Another observation of fundamental importance is the prolonged remaining of the bismuth at the site of injection, i. e., the formation of a socalled depot. Following an intramuscular injection the bismuth can be traced radiographically in the muscle four to five days later. Levi and Bing (3), who have gathered statistics along these lines, advise repeated radiography to ensure the earliest possible discovery of a retarded resorption. Wolffer, who also experimented on the same question, found that the bismuth could be traced in the muscle of rabbits as late as thirty-four days after the injection. While arsphenamine solutions and mercury emulsions occasionally remain at the site of injection unaltered for weeks and may lead to a necrotic process, the prolonged remaining at one site of the bismuth compounds has hitherto proved to be a methodical though very slow process of resorption, with new formation of capillaries (Mueller, Blass, Kratzenstein). In our experience the danger of accumulation of bismuth is small, provided the initial dose is carefully studied and one feels one's way by gradually increasing the dose and controlling the blood picture. Storing of the bismuth takes place chiefly in the liver, kidneys, cerebrum and salivary glands. Much of this accumulation depends on the particular bismuth compound. We have not seen disturbances of this kind with the oxybenzoic acid compound. Stomatitis requires attention. Milian (4) reported inflammation of the buccal mucosa in ten per cent. of his cases. We have generally managed to avoid pronounced stomatitis by carefully groping our way with new patients and slowly increasing the amounts given. Rises in temperature cannot always be avoided. Particularly in secondary eruptions our injections always provoked rise in temperature, which in these cases was probably due to the sudden flooding of the system with toxic material, spirochete masses, etc. H. Mueller (1) reports a case in which the bismuth sodium potassium tartrate caused a rise of the temperature up to 40° C. This case we believe may be due to the particular compound.

In all cases we hold that an exact control of the blood picture is essential during all antisyphilitic medication. This is frequently neglected though it is a reliable measure for judging the status of the patient. A sudden decrease of the white cells, particularly the lymphocytes, is just as vital as a sudden drop of the red count and demands immediate interruption of the medication and rest for the patient. A temporary general stimulation with the Alpine sun lamp during these stages has proved satisfactory. As a further measure for controlling the biological reaction of the patient we have made the control of the sinking rapidity of the red blood cells a routine measure.

As to the damage to the kidneys much has been reported in the literature of the last years. Day found albumin and granulated cylinders after intravenous injections of citrate of bismuth. Blum observed that the kidney damage was always concomitant with stomatitis and enteritis and that these represent the primary disturbance, an opinion which seems justified and has been reported by Mueller (1). We have managed to avoid these disturbances by a careful groping dosage and by frequently examining not only the urine but also the centrifuged deposit as advised by Felke (5). As to the influence of bismuth compounds on the serum reactions we have seen a pronounced and lasting influence of the oxybenzoic acid compound (bismogenol) on the Wassermann and Sachs-Georgi reactions. As our observation period only covers three years we can only state that the clinical results obtained with bismuth medication in all stages of syphilis have been satisfactory and should encourage to further experiments and observations. In all cases of idiosyncrasy against arsphenamine and mercury attempts with bismuth medication are indicated and justified.

X Ray Treatment of Syphilitic Interstitial Keratitis.—The following conclusions are drawn by T. L. De Courcy and J. H. Mather (*British Medical Journal*, January 5, 1924):

1. In syphilitic interstitial keratitus, x rays in weak doses have an undoubted effect in cutting short the early stages of infiltration into the deeper corneal layers.

2. The earlier the stage of the disease at which this treatment is started, the more rapid the improvement and the more satisfactory the results.

3. The younger the patient the better the reaction to x rays. In the cases treated children reacted more rapidly than young adults, while in older people the reaction was less satisfactory.

4. It is in the relief of pain, photophobia, and lacrymation that x rays show the most striking results. The acute stage is also much shortened by checking infiltration and vascularization.

5. The opacities in young subjects are undoubtedly benefited by x rays.

6. In no case was any damage done to the eye or the surrounding tissues, and the patients complained of no inconvenience during the treatment.

7. Small doses only of x rays are necessary.

8. X rays should be used as an aid to, but should not take the place of, local, antisyphilitic, and general treatment.

9. The value of small doses of x rays shown in interstitial keratitis justifies their trial in certain chronic eye diseases where treatment has been disappointing, such as the painful blind glaucomatous eye and scleritis of the aged. Further, a safe and more stabilized technic, such as that used by the authors, holds out hope of better results in many eye conditions, both chronic and acute.

Gastrointestinal Symposium

Medical Journal and Record

PUBLISHED SEMIMONTHLY BY

A. R. ELLIOTT PUBLISHING COMPANY, 53 PARK PLACE, NEW YORK, N. Y.

NEW YORK, WEDNESDAY, OCTOBER 1, 1924

Mimicry of Gastroduodenal Ulceration by Disease of the Appendix

*Lymphatic Drainage from the Ileocecal Region to the Upper Abdomen**

CHARLES GORDON HEYD, M.D.,

New York

From the biological point of view the gastrointestinal tract represents the oldest morphological structure in the body. In its phylogenetic development it has undergone remarkable transpositions and changes in morphology but it is essentially an autonomous muscular tube capable of variations in the rate and amplitude and rhythmicity of its contractions. The association of the central nervous system with the gastrointestinal tube has been of comparatively recent origin as is evidenced by the fact that upon complete section of the vagus and splanchnic nerve connections the normal processes of digestion are carried on in a fairly satisfactory manner. It seems unnecessary to enter into any detailed or intricate explanation of the hypothesis of vagus and splanchnic tone to account for some of the many aberrations of function which we find in gastrointestinal pathology. The alimentary tract throughout its entire course exhibits variations in specific function and reacts in a somewhat definite manner to irritation and to a variety of pathological conditions. As a general proposition the gut tube exhibits two fundamental functions, a, the function of secretion, and b, the function of motion. In considering the former we are impressed with the duplication of secretory activity and there seems to be a large margin of safety (1) in regard to the essential digestive enzymes. It is in disturbance of motor function that we meet the most diverse symptomatology. For while the secretory function may fail so long as the gut tube possesses the property of onward propulsion of the contained material its efficiency as a digestive apparatus is fairly well maintained. However, the gastrointestinal tube is not a rigid pipe through which material flows under the influence of gravity. Its behavior is essentially not that of a rigid tube (2). Gaskell (3) has drawn attention to the peculiar living property of the gut tube in that "every point of the intestine is in a state of activity which can be played upon and modified by impulses arriving at it from all portions of the gut above and below." The variously designated portions of the gastrointestinal tract exhibit wide variability in contractions, rhythmicity, irritability and tone, yet contractility is autonomous and the mechanism for peristalsis is intrinsically present in all parts of the alimentary tract. Alvarez (4) applied the idea of gradients of rhythmicity when he stated that "in the stomach and intestines contents move from regions of high rhythmicity, high irritability and high tone to regions of low rhythmicity, low irritability and low tone."

At certain points throughout its course we find certain specialized connections of nerve tissue which Keith has described and which behave in every way similar to the nodal tissue in the heart. Four of these nodal points are definitely established and four others may be surmised with reasonable certainty. Seriatim they are: 1, at the junction of the pharynx and esophagus (5); 2, at the cardiac orifice; 3, just beyond the pylorus near the ampulla of Vater; 4, at the duodenojejunal flexure; 5, the ileocecal sphincter; 6, about the midpoint of the transverse colon; 7, the junction of the pelvic colon and rectum; and 8, within the anal ring. The muscular activity of the gut tube is dependent, therefore, upon an intrinsic rhythmic tone with autonomous contractility and hence the contracting of any portion of the intestine will depend upon its tone, conductivity, irritability and intrinsic contractile rate. All muscular activity is influenced, in a large degree, by the available blood supply. Inflammatory processes are associated with hyperemia, and local cell life or the intrinsic metabolism of the cell is accelerated by nearby inflammatory processes (6) and hence one would expect in any inflammatory condition in the region of the cecum an increase in the irritability of the small intestinal tract above the point of inflammation. "An irritating lesion slows the progress of food coming toward it from above and hastens the progress of food that has passed it" (7).

The study of gastrointestinal symptomatology is an attempt to correlate symptoms with disturbances

*Read before the American Gastroenterological Association, Atlantic City, N. J., May 5, 1924. From the Department of Surgery, New York Postgraduate Medical School and Hospital.

in the orderly progression of material through the gut tube. Inferentially, this material may be accelerated in its passage, delayed, retained or obstructed. In the more gross manifestation of motor obstruction the symptoms are pronounced and clear cut, but when the symptoms are so protean as nausea, regurgitation, heartburn, pyrosis, vomiting, vague abdominal distress, they are so general and lacking in specific characteristics as to be difficult of interpretation. Yet, is it not with these minor fluctuations of gastrointestinal conduction that we are mostly concerned and which come to the physician under the generic title dyspepsia, but which represent the beginning of organic changes in the gut tube?

The stomach exercises, in the main, two fundamental functions, secretion and motion, and it is in variations in the degree of motor deficiencies that we look for the interpretation of the gastric symptomatology of chronically diseased appendix. Morphologically and physiologically the stomach divides itself into three parts: the upper or cardiac portion acting as a food reservoir; the antral portion concerning itself with active churning and muscular contraction, and the third portion or canalis gastricus being the delivery tube into the duodenum.

There is an intimate physiological relationship between the pylorus and the ileocecal sphincter. There is a great similarity in the functions exercised by both orifices. In both places we have a natural point of stasis—gastric retardation and ileal retardation. The delivery of chyme into the duodenum is followed by the delivery of chyle into the cecum and conversely the emptying of the ileum brings about a gastric evacuation. Hurst (8) demonstrated that the ingestion of food causes material to pass through the ileocecal valve and Cole (9) has drawn attention to the fact that he has observed a reactivation of duodenal peristalsis when the terminal ileum emptied its contents into the cecum. This gastroileal reflex has been closely studied by Keith, Hurst, Cole, Barclay and Alvarez and is of marked importance in maintaining the normal and natural retardation of food in the small intestines. At the ileocecal valve we have a change in chemical reaction from alkalinity to acidity. We have the greatest degree of bacterial life taking place in a medium of greatest fluidity and in an area that stands out by reason of the predominance of its lymphoid tissue.

From the surgical viewpoint the appendix represents an organ with a naturally deficient drainage and a mechanism that is at all times prone to low grade infections or irritations of bacterial origin. Adami (10) and his coworkers—Nichols and Ford—have demonstrated the continuous passage of leucocytes through the intestinal wall into the mesenteric lymph nodes and lymphatic system. These leucocytes carry bacteria or ingested particles of pigment or fat droplets. Obviously, most of the bacteria and leucocytes undergo lysis or destruction in Peyer's patches or in the first regional lymphatic glands. Occasionally a few, reduced in virulence, pass on into the portal system and find lodgment in the liver, thereby setting up irritating foci with the production of fibrous tissue. The bacteria do not proliferate in the liver but by their lysis produce irritating chemical substances which bring about fibrous tissue replacement. If the transmigration of bacteria through an intestinal wall is found as an occasional occurrence under apparently normal or healthy conditions the mechanism must be exalted in inflammatory conditions of the gastrointestinal tract. Conditions of irritation of the mucosa, types of colitis and ulcerated conditions of the alimentary tract must facilitate and accelerate this leucocytic migration.

Probably no organ within the abdomen is capable of producing such widespread peritoneal reactions and in so many diverse ways as an acutely infected appendix. The degree of peritoneal reaction is proportional to the acuity of the infection and obviously, minor degrees of infection of the appendix will produce the same character of peritoneal reaction which will vary in quality and kind only. Long before there is a perforation or an extravasation of intestinal contents from a diseased appendix we have a peritoneal irritation represented in an advancing zone of nonpathogenic anaerobic bacteria, the purpose of which is to bring forth the normal fibrinoplastic reaction of the peritoneum. In and about this infected area the omentum becomes attached or contiguous with it. The intestinal coils are agglutinated and held so that there is a resistant wall of infiltrated leucocytic fibrinoplastic material. The future of these barriers in the ordinary nonlethal, nonsurgical cases is that they are ordinarily absorbed, leaving behind, however, some memorabilia in the form of adhesions which become vascularized and produce varying degrees of physiological disability. The adhesive reaction in or about an area of infection may therefore be histologically divided into two stages, the difference between the two being one of vascularity and organization. The first stage of an adhesive reaction consists in an outpouring of fibrinoplastic material which is nonorganized, does not contain bloodvessels, and from which no lymphatic absorption takes place. After a variable interval this fibrinoplastic material is organized and converted into an absorbing, vascularized form of newly made peritoneal tissue. The omentum, also being peculiar in its vascularity, contains many converging veins of great length; these are thin walled and not adequately supported by fibrous connective sustaining tissue. Eiselberg (11) demonstrated how rapidly these veins are thrombosed and an epiploitis after hernia operations is a well substantiated clinical observation. Wilkie demonstrated the ease with which injury and thrombosis of the portal vein occurred. Upon mere ligation of some of the omental veins he produced punctiform hemorrhages in the stomach in thirty per cent. of the cases and in fifty per cent. hemorrhagic infarcts in the liver. This was particularly liable to occur following the ingestion of food for there is contraction and dilatation of the veins of the stomach and small intestine during the varied cycles of digestion. With the loaded stomach the gastric veins attain a diameter four times greater than that which obtains in a fasting stomach. If aseptic thrombi in omental veins showed these preeminent tendencies toward upper abdominal embolism how much greater must be this embolic tendency in a septic thrombosis. There is no definitely established route for the portal blood for Wilkie (12) was able to demonstrate that the course of the blood through the veins of the

portal system was capable of being diverted from the usual or direct anatomical route. The injection of oil globules in the veins at the right hand fringe of the omentum could be followed directly to the right gastroepiploic vein and, as a rule, the oil globules were carried to the liver directly. However, the low blood pressure within the portal system together with the absence of valves within the venous tributaries would permit occasional divarications in the course traversed by the venous blood from the omental veins. Oil globules could be made (by coughing or holding the breath) to move into the left gastroepiploic vein to form splenic infarct or to flow through the transverse gastric veins to the coronary vein at the lesser curvature.

In the course of our studies on changes in the liver associated or coincident with chronic abdominal inflammation we were able to demonstrate with remarkable frequency the association of periportal infiltration of either round cell or polymorphonuclear cell type in conditions of chronic disease of the appendix (27). The association of thrombosis of the periportal vein with acute septic conditions of the right lower quadrant has been of such frequent occurrence as to require no comment (13). We are inclined to believe that there is a constant absorption of bacteria themselves or their byproducts by means of the venous tributaries of the portal system and their subsequent conduction to the liver and upper abdomen. Feutterer (14) was able to recover bacteria injected into the appendiceal vein two minutes later in the bile. Braithwaite, however, was able to inject the lymph channels from the cecum up to and over the pancreas and stain the lymph glands in the cresent fold of the duodenum on the anterior surface of the pancreas. Franke (15) was able to inject the postpancreatic group of glands in that area between the duct of Santorini and the duct of Wirsung and if these two authors by experiments, one from below and the other from above, can infect the glands of the pancreas both front and back, then certainly the stomach and duodenum could be infected from any chronic abdominal infection by means of lymphatic anastomosis as depicted by Bartells. Craig (16) in a study on the lymphatics of the intestines was able to carry infectious material from the first and second portion of the duodenum up to and along the lesser curvature of the stomach. Franke (15), Sweet (17) and Pfeiffer have shown the intimate association of the appendix through lymphatic channels with the hilus of the right kidney. An interesting clinical experiment by Braithwaite (18) was the feeding of a kitten brought up on sterile food with material obtained from tuberculous glands in the human and on autopsy finding tuberculous adenitis extending from the cecum up to the group of glands beneath the antrum of the stomach, and he adduced that while most of the lymph from the ileocecal angle flows to the lumbar group of glands some may, however, pass up to and beyond the pancreas on to the wall of the pylorus or even stain glands of the cystic duct. Furthermore, Braithwaite was able to outline lymphatic conduction from the area of the ileocecal angle to the subpyloric group of glands and drew attention to involvement of the subpyloric glands in chronic infections of the appendix.

A great deal of confusion exists as to what is a chronic appendicitis. A pathologist has certain definite criteria that he will define as being essential for the pathological diagnosis of a chronically diseased appendix. A surgeon, thinking in clinical terms, is more likely to be impressed with the gross macroscopical picture of the appendix as he finds it than he is with the description of microscopical changes.

Chronic appendicitis may be defined as an appendix that is habitually infected and subject to recurrent inflammation. In studying our histories in operatively proved cases of chronic appendicitis we have arranged the symptoms into four groups: Group 1, patients with symptoms that were purely local and confined to the right lower quadrant; group 2, patients with symptoms that were manifestly reflex and referred to the upper abdomen, particularly to the stomach; group 3, patients with symptoms of upper abdominal distress similar to group 2 plus hematemesis; group 4, patients with symptoms of right lower quadrant pain plus irritable colon.

An occasional expression of a chronically diseased appendix is an irritable colon, the patient having a bowel movement immediately after the ingestion of food and due to a hypersensitive and hyperacting colon together with a loss of the normal retardation of ileal contents at the ileocecal valve. That there is a type of low grade inflammation of the appendix associated with fibrous or obliterative changes in the appendix and unaccompanied by local pain is an established fact. Pain confined to the region of the appendix and due to inflammatory changes within the appendix will depend primarily upon the degree of virulence and the amount of retention of appendiceal contents. This retention of appendiceal contents may be due to inflammations with occlusion as the result of edema or to alternate constriction formation as a result of previous inflammations. A common cause of partial retention of appendiceal contents is from angulation or kinking associated with low grade typhilitis or periappendicitis. "The distinction between the two portions of the appendix —the one thin, pale and empty, the other turgid, grossly enlarged and overful, is striking. At the junction between the two a firm band is found. In all forms its lumen is obstructed either by definite constriction or external attachments" (19).

It is surprising to note that fully one third of our patients complaining of upper abdominal distress had had previous attacks of abdominal pain of rather an acute nature, which could be reasonably interpreted as being due to appendicitis. Local pain in the area of McBurney's point was either present or given in the history of approximately eighty per cent. of all of the cases and when present at the time of examination was almost invariably associated with tenderness on fluoroscopic examination. The upper abdominal symptoms embraced pain which was more frequently in or about the region of the navel than above. It was a pain of variable intensity, more often a complaint of distress with a definite radiation downward and to the right lower quadrant and the patient in indicating the site of the pain would ordinarily place the entire hand with the centre of the palm overriding the umbilicus. The pain was manifestly made worse by the inges-

tion of food and fully fifty per cent. of the cases indicated that certain articles of food were capable of making the pain worse (20). There was no constancy in these articles of diet and depending upon the patient's memory and observation an article that could be eaten with comparative freedom at one time would on another occasion produce a greater degree of pain. There was no periodical or rhythmic recurrence of the pain in relation to fixed hours of eating. There were periods of days when there was no distress whatsoever and symptoms which might be present on one day would be absent on the following day and thereafter for a variable period of a week to ten days or six weeks. Throughout this history there was at all times a capriciousness as to the time of onset of symptoms and their relation to the time of food ingestion and in general there was exhibited a variability of symptoms that is not present in ulcer. Vomiting is after all a rare sign of ulcer of the gastroduodenal segment yet in appendiceal dyspepsia it is probably the most constant of all.

Not an uncommon history is that of pain, coming on suddenly, irrespective of the quality of the food, epigastric in type, radiating downward to the right lower quadrant and followed by repeated attempts at vomiting. The material vomited is first food material and then glairy white mucoid material, rarely is it tinged with duodenal reflux. In gastroduodenal ulceration we have ordinarily two processes occurring simultaneously—a destruction of tissue and a healing of tissue by fibrous tissue replacement—the interplay of these two factors depending upon the age and concomitant tissue reaction of the individual. The production and healing, or cicatrization of an ulcer requires a definite interval of time and if an ulcer is producing symptoms the outstanding feature in the symptomatology is the regularity of the symptoms produced and the more or less constant repetition day after day over a period of time under the same conditions of food intake. The element of regularity is exhibited in approximately ninety per cent. (21) of all true gastroduodenal ulcers. If we analyze a sufficiently large group of cases we will find that there are four symptoms which are particularly noteworthy by reason of their constancy, their periodicity and their precise and regular daily recurrence: 1, pain, truly epigastric, of variable intensity, is almost always present; 2, the onset of this pain bears a definite time relationship to the ingestion of food; 3, this time relationship after being established is periodical in recurrence day after day upon the ingestion of the same articles of food; and, 4, a definite chronicity usually estimated by weeks. It is the absence of regularity in the symptomatology of the chronically diseased appendix that differentiates it from gastroduodenal ulceration.

It is interesting to note that of five hundred cases reported by Deaver (22) 161 patients were operated upon in an acute phase of the disease and the common observation of the patient with chronic dyspepsia of many years' duration being entirely cured following an appendectomy for acute appendicitis is commonplace and requires no comment. Furthermore, the same author in regard to the specific question as to the relationship of disease of the gall bladder and appendix found that ninety per cent. of his diseased gallbladders had demonstrable pathological changes in the appendix and sixty-one per cent. of his ulcer cases had pathological changes in the appendix.

Moynihan (23) and later Braithwaite (18) have described three stigmata of a chronically diseased appendix that may ordinarily be observed through an upper abdominal incision: 1, the "tumultuous contracture" of the antral portion of the stomach. One may see during the laparotomy marked incisural contractures dividing the cardiac from the antral portion of the stomach. These gastric indentures remain fixed for a short period of time and although they may occur in other conditions they are more habitually expressed in a stomach that shows hyperirritability as the result of a chonically diseased appendix. 2. The remarkable hypervascularization of the pylorus, and, 3, hyperplasia of the subpyloric group of glands. These glands are beautifully pink in color, and represent a mild hyperplasia. We have observed in a number of cases a thin, vascularized film extending across the pylorus that may be elevated with a thumb forceps, is nowhere restraining and is nowhere organized. In connection with the contraction above we have thought that the pyloric ring itself exhibited an increased tonus. This is a personal equation and is open to wide interpretation.

An associated finding in many cases is the fact that the gallbladder adjacent to this hypervascularized pylorus shows suggestive signs, at any rate, of a beginning pathological change. The wall is somewhat thickened, the green color is faded into a blue and around the area occupied by the gallbladder are white radiating lines of beginning interstitial hepatitis or glissonitis. Eusterman (24) reports 1,078 cases of gastroduodenal ulcer with forty per cent. exhibiting disease of the appendix and 9.7 per cent. disease of the gallbladder. Mayo (25) reports that the average duration from the onset of symptoms to operation in appendicitis, cholecystitis and cholelithiasis reveals respectively two, four and nine tenths, and six and five tenths years. The average case of cholecystitis lies between the average in appendicitis and cholelithiasis.

In the chronic appendix that has produced the ulcer syndrome we have noticed the uniform turgescence of the appendix when viewed as a whole.

In exposing the appendix we have noted a number of changes which we estimate as criteria of pathological change in the appendix: 1, the alternate areas of constriction and dilatation occurring throughout the appendix, or in its distal half which we have interpreted as being due to intermittent attacks of inflammation with cicatrization; 2, a marked hypervascularization of the appendix; 3, an obliterative process usually involving the terminal centimetre and proximal to the obliteration a bulbous distention; 4, the presence of adhesions, usually on the inferior external surface and ordinarily producing a kinking with vascular and luminal obstruction; 5, the presence of a fair degree of glandular hyperplasia in the group of glands between the ascending colon and terminal ileum.

In conclusion, if the appendix were chronically infected and capable of deranging the physiology of

the upper abdomen we would expect that there might be certain liver changes in long continued inflammation. We believe, from the material that we have collected, that long continued infection of the appendix is associated with certain pathological findings in the liver (26), that these changes in the very mild cases embrace a periportal infiltration, first of round cells, later polymorphonuclear cells and finally some degree of hepatic degeneration with fibrous tissue replacement, giving a picture of a mild degree of periportal fibrosis. In more chronic cases, or those of somewhat greater infectivity but still essentially chronic cases, in addition to the periportal infiltration there is peribiliary infiltration and the round cell infiltrative process may pass from the periportal to the peribiliary systems. In this group we invariably find the gallbladder exhibiting certain early pathological changes and the liver exhibiting the surface marking of an interstitial hepatitis.

Carcinoma of the Papilla of Vater*

MAX EINHORN, M.D.,
and DeWITT STETTEN, M.D.,
New York

Carcinoma of the papilla of Vater is today a fairly well recognized pathological and clinical entity, and in the past decade a considerable number of cases have been observed and reported, showing that the disease is not such a rarity as has been supposed. The lesion tends to produce very marked and characteristic symptoms even in its incipiency and, according to Kausch (1), because of its peculiar site, permits of the possibility of earlier diagnosis than almost any other form of internal cancer. Further, these carcinomata seem to be tumors of a relatively benign character, as shown by their slow growth and late metastases. In spite of these facts, the history of the treatment of this disease has been anything but a brilliant one, while the record to date of the radical operative attempts even in early, unadvanced cases is almost disastrous. It is in the hope of stimulating further research toward the goal of improving the results of radical excision that the following case is reported and the appended suggestions made.

Case.—J. H. S., male, aged thirty-eight, was admitted to the Lenox Hill Hospital on June 12, 1923. There had been no history of typhoid fever, but as a child of eight or nine years he had had an intermittent fever with jaundice which was diagnosed as malaria. Since childhood he had suffered from migraine attacks. For many years he had complained of hyperacidity. In March, 1923, he had an attack of severe epigastric pain radiating through to the back. This pain lasted about three hours and there was no vomiting. A second, similar attack followed about three weeks later, and a third attack one week after that. The last or fourth attack began three and a half weeks before admission to the hospital, with the same type of pain, though more severe. The pain also lasted much longer—nearly twelve hours. There was no fever or vomiting, but about two weeks after the attack or about one week before admission, he became slightly jaundiced. This jaundice gradually increased and then began to subside. He had lost no weight. Patient was a large man, well nourished, weighing 240 pounds. When first seen the patient showed slight jaundice with a definite subicteric tint to the sclera and skin. There was some sensitiveness and rigidity in the right hypochondrium, although no mass was palpable. Temperature and pulse were normal. The urine showed a faint trace of bile. Gastric contents showed hydrochloric acid, 40; total acidity, 65. String test showed a slight blood stain in the stomach. Bile obtained with the duodenal tube in the fasting condition was turbid and contained pus corpuscles and a considerable amount of cholesterin crystals. Röntgenographic examination showed no evidence of cholelithiasis.

With a provisional diagnosis of subacute cholecystitis with probable cholelithiasis, operation was performed on June 16, 1923. Through a typical right hypochondriac incision a much distended, thickened and injected gallbladder was exposed. It showed definite evidences of active inflammation. The organ was unusually large and tense, but no adhesions to it were noted. No calculi could be palpated in the gallbladder, ducts, or at the papilla. There was no dilatation of the hepatic or common bile ducts. The foramen of Winslow was patent and the pancreas was not indurated. The liver appeared normal. There was no evidence of tumor, ulceration or cicatrization in the stomach, pylorus or duodenum. The pylorus was widely patent. The appendix lay to the inner side of the cecum, was somewhat long and bound down by dense adhesions. A typical cholecystectomy was done, during which it was noted that the cystic duct was rather friable. The appendix was also removed. A gauze tampon was placed in the liver bed of the gallbladder and a cigarette drain into Morison's pouch, both being surrounded by a rubber dam. The abdominal wound was closed in the usual fashion. Gross examination of the gallbladder showed it to be a much thickened, distended organ with a definitely injected serosa and a papillary, mossy mucous membrane which suggested tripe. The color of the mucous membrane was yellowish. The gallbladder contained a thick, greenish, turbid bile. The appendix showed the usual changes of a chronic appendicitis. The microscopic report on the two organs was chronic cholecystitis and chronic catarrhal appendicitis.

There was slight biliary drainage from the tampons for a few days, but this ceased after about the

*Read at the Twenty-Seventh Annual Meeting of the American Gastroenterological Association, May 5-6, 1924.

tenth day, the patient making what appeared to be an uneventful recovery. The slight jaundice existing before the operation entirely disappeared and the sutured portion of the wound healed by primary union. About three weeks after operation the patient complained of a little gastric distress and hyperacidity, and there were slight evening rises of temperature to about 100°. On July 9th, twenty-three days after the operation, the day patient was to leave the hospital, there was a sudden profuse, biliary drainage from the wound, suggestive of a suddenly developing obstruction. The patient had clay colored stools and the sinus continued to discharge clear bile in profuse quantities until July 28, 1923, two days after he left the hospital, when the drainage ceased as suddenly as it had begun, suggesting that the obstruction had been relieved. While the biliary drainage persisted the patient became rather depressed and lost forty-six pounds in weight. The patient now began to improve. His appetite was good, his stools were normal, and his mental condition was much better. By September 15th he had regained eleven pounds in weight. About this time he had an attack of discomfort in the epigastrium, but no real pain. Associated with this attack there was some fever, flatulence and offensive stools. Colonic irrigations were taken and he again improved after about two weeks. Afternoon temperatures again recurred, with chilly sensations in the morning. The stools were again light colored and the patient claimed his urine was darker. Patient was seen on October 12th and readmitted to the hospital. His temperature was 102.2° and his pulse 96. He was obviously ill. His weight was now 199 pounds. The abdominal scar was thoroughly healed. There was no abdominal sensitiveness or other definite local abdominal signs. He was not jaundiced. He was kept under observation until November 1st, during which time he had several sharp rises of temperature up to 102.5° to 104°, preceded by chilly sensations or really definite chills. Associated with the true chills were rather marked nausea and severe retching. Between the rises of temperature there were afebrile periods varying from one to four days. He did not become icteric and the urine was examined repeatedly for bile and was always negative. The stools were light colored but bile was found in them. The Widal examination was negative. The blood smear was negative for plasmodia. The white blood cell count was 10,200, with 75 per cent. polynuclears. The blood culture was sterile. Röntgenographic examination showed a widening of the space between the lower border of the liver and the right diaphragm and some irregularity of the under surface of the liver, but no direct evidence of cholelithiasis. From October 13th to October 28th, medical biliary drainage was instituted for both therapeutic and diagnostic purposes. It was performed daily, as follows, the various liver stimulants, magnesium sulphate, peptone, glucose and olive oil being used.

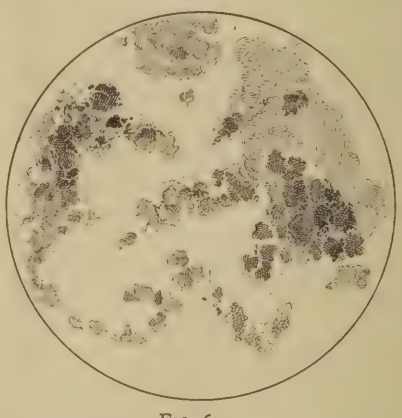

Fig. 6

Fig. 1.—Microscopic picture of the tiny blackish concretions of pinhead size found in bile aspirated by duodenal tube. Brownish red, somewhat rounded crystals resembling bunchberries.

Fig. 2.—Cholesterin and calcium bilirubin crystals and mucus found in bile aspirated by duodenal tube.

Fig. 3.—Sandlike particles of cholesterin and calcium bilirubin crystals found in bile aspirated by duodenal tube.

Fig. 6.—Microscopic picture of pinhead sized concretion in bile flowing out of common bile duct at operation. Same bunchberry appearance of crystals noted.

October 13.—Fasting: Light watery yellow, very slightly turbid. Alkalinity =25; Amylopsin=3; Steapsin =2; Trypsin= 5. After magnesium sulphate (twenty-five per cent.) sixty c. c.: Moderate color reaction beginning at ten minutes and ending at thirty-one minutes. Total return sixty c. c. in thirty-one minutes.

October 14.—Fasting: Dark yellow, very turbid. Alkalinity=15. After peptone (five per cent.) sixty c. c.: Slight double color reaction: 1. Beginning at ten minutes and ending at twenty-one minutes, amount being twenty-five c. c. 2. Beginning at twenty-eight minutes and ending at thirty-three minutes, amount being thirty c. c. Total sixty-five c. c. in thirty-three minutes. Calcium bilirubin and cholesterin crystals, also mucus found.

October 15.—After glucose (twenty-five per cent.) sixty c. c.: Good color reaction, beginning at sixteen minutes and ending at twenty-eight minutes.

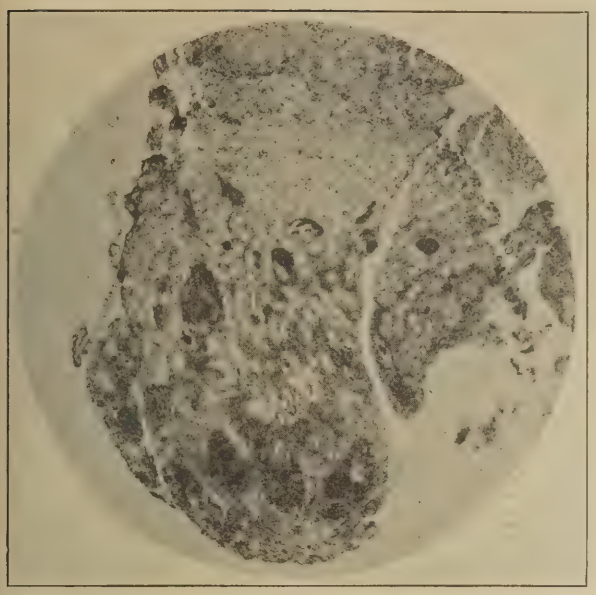

FIG. 4.—Microscopic appearance of tumor infiltrating duodenum (low power). Tissue taken from edge of tumor. Note general topography, submucous hemorrhages, normal glandular structure and tumor tissue beneath, with some necrosis of the more superficial area.

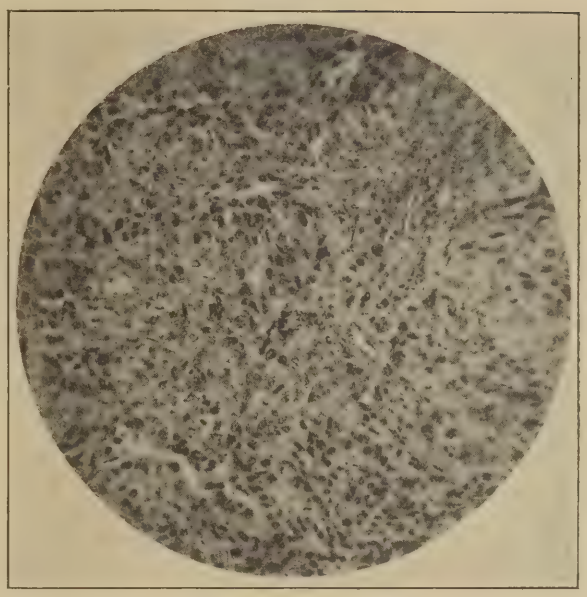

FIG. 5.—Microscopic appearance of tumor tissue (high power). Note mitotic figures, round cell infiltration, and aberrant ducts.

amount being thirty c. c. Total fifty c. c. in thirty-five minutes. Cholesterin and calcium bilirubin crystals, also mucus present.

October 16.—After peptone (five per cent.) sixty c. c.: Good color reaction, beginning at fourteen and ending at twenty-one minutes. Total fifty c. c. in twenty-two minutes. Tiny sandlike concretions found containing cholesterin and calcium bilirubin crystals, also mucus.

October 17.—After olive oil, thirty c. c.: Double color reaction: 1. Beginning at ten and ending at fifteen minutes, amount being thirty c. c. 2. Beginning at eighteen and ending at twenty-five minutes. Total sixty-five c. c. in twenty-five minutes. Sand concretions with calcium bilirubin crystals found.

October 18.—Fasting: Dark brownish yellow, very turbid. Alkalinity=20. After peptone (five per cent.) sixty c. c.: Slight color reaction beginning at twenty and ending at thirty-eight minutes; amount thirty c. c. Total forty-five c. c. in thirty-eight minutes. Brown and blackish sandlike particles found.

October 19.—Fasting: Dark brownish yellow, very turbid. Alkalinity=20. After magnesium sulphate (twenty-five per cent.) sixty c. c.: No color reaction present. Total thirty-five c. c. in twenty-two minutes.

October 20.—After glucose (twenty-five per cent.) sixty c. c.: Trace of double color reaction present: 1. Beginning at ten and ending at sixteen minutes, amount being fifteen c. c. 2. Beginning at seventeen and ending at twenty minutes, amount being fifteen c. c. Total thirty c. c. in twenty minutes. Black sandlike particles found.

October 21.—After glucose (twenty-five per cent.) sixty c. c.: No color reaction present. Total forty c. c. in forty minutes.

October 22.—Fasting: Dark brownish yellow, very turbid. After glucose (twenty-five per cent.) sixty c. c.: No color reaction present. Total fifty c. c. in twenty minutes.

October 23.—Fasting: Dark brownish yellow, very turbid. Alkalinity=30; Amylopsin=6; Steapsin=2; Trypsin=1. After glucose (twenty-five per cent.) sixty c. c.: Moderate color reaction present, beginning at sixteen and ending at twenty-five minutes, amount being thirty-five c. c. Total sixty c. c. in thirty-five minutes. All specimens were clear. Black sandlike concretions present.

October 24.—Fasting: Dark yellow, very turbid. Alkalinity=20. After glucose (twenty-five per cent) sixty c. c.: Slight color reaction present, beginning at fifteen and ending at twenty minutes, amount being thirty c. c. Total fifty c. c. in thirty minutes. No black sandlike particles seen today.

October 25.—Fasting: Dark brownish yellow, very turbid. Alkalinity=25. After glucose (twenty-five per cent.) sixty c. c.: No color reaction present. Total sixty c. c. in forty minutes.

October 26.—Fasting: Dark brownish yellow, very turbid. Alkalinity=20. After glucose (twenty-five per cent.) sixty c. c.: No color reaction present. Total thirty-five c. c. in forty-seven minutes.

October 28.—Fasting: Dark brownish yellow, turbid. Alkalinity=25. After glucose (twenty-five per cent.) sixty c. c.: No color reaction present. Total thirty-five c. c. in eighteen minutes. Blackish sandlike particles, containing mucus, calcium bilirubin and cholesterin crystals.

It will be seen from these findings that for the first four days all the liver stimulants, especially glucose, produced a good color reaction or dark colored bile, in spite of a previous cholecystectomy. From October 18th on the same liver stimulants began to show weaker reactions and eventually none at all, the reaction from glucose persisting the longest. This clearly indicated a disturbance of liver function. The flow of bile was free and quite normal in quantity. In the fasting state, it was, at times, rather turbid. In it there were often found tiny sandlike concretions, usually of blackish color. Microscopically these were found to be conglomerations of calcium bilirubin and cholesterin crystals and mucus. (Figs. 1, 2, and 3.) The duodenal contents contained no blood

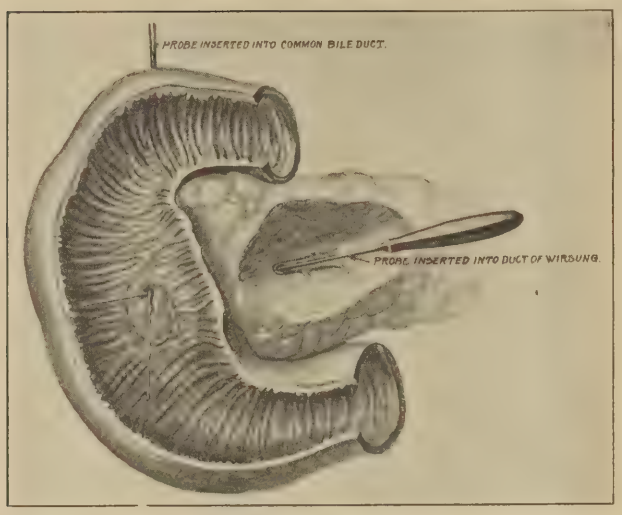

Fig. 7.—Gross appearance of carcinoma of papilla of Vater with probes inserted into the common bile duct and duct of Wirsung.

and on culture showed no typhoid bacilli. No therapeutic result was noted from this biliary drainage with the duodenal tube.

After numerous consultations, reoperation was decided upon with a provisional diagnosis of infectious cholangitis, probably due to a concretion in the common bile duct, possibly overlooked at the first operation. This impression was substantiated by the history of the sudden postoperative development of profuse biliary drainage from the wound and its quite as sudden cessation, suggesting a movable calculus in the choledochus. Operation was performed on November 2, 1923. The old scar was excised and the usual dense adhesions of the structures in the right hypochondrium were found. No pathology was noted in the liver, stomach or pylorus. With some difficulty the common bile duct was exposed and found to be somewhat shortened by contraction, decidedly dilated, and with a definitely thickened wall. The pancreas seemed slightly indurated, and a rather firm gland was seen and palpated near the junction of the common bile duct and duodenum. On palpating the hepatic and common bile ducts no calculi were felt. The common bile duct was then opened between two guy sutures and a rather unusual amount of exceptionally light colored bile welled out under considerable pressure, definitely indicative of, at least, a relative obstruction, to which the biliary system had sufficiently adapted itself to prevent a recognizable icterus. The bile contained numerous black, granular concretions, similar to, but rather larger in size than those found in the duodenal contents previously. A culture of the bile was taken. An attempt was made to probe the common bile duct but this was unsuccessful. At the tip of the probe, rather low down in the pancreas, was felt à hard, rounded nodule about the size of the distal phalanx of the little finger, which at first gave the impression of being a calculus impacted at the papilla. Attempts to dislodge this mass with the probe, forceps, or by milking upwards were unsuccessful, so a transverse incision was made through the duodenum immediately opposite the mass. On examination it was found that this mass was not a calculus but a hard, infiltrated ulceration with a punched out, craterlike floor and with jagged, elevated and everted edges. The ulcer just about admitted the tip of the examining finger and apparently corresponded to the papilla. This mass was densely adherent to the pancreas and the infiltration extended into the pancreatic tissue. Just to the right of the head of the pancreas and adherent to it, was palpated a separate, hard nodule which seemed to be an infiltrated mesenteric lymph gland. The probe, passed through the opening in the common bile duct, could now be guided into the duodenum, passing almost directly through the centre of the ulcer. The probe was moved about to dilate the duodenal opening of the common bile duct and several specimens of the edges of the ulcer were taken for examination by means of a punch. The duodenal incision was closed in the usual manner and the wound in the common bile duct was partially sutured. Proper drainage was instituted and the abdominal wound sutured.

Gross examination of the tissue removed from the ulcer at the papilla showed it to be of rather firm consistency and suggestive of malignancy. The microscopic examination confirmed this impression. It was a typical adenocarcinoma of the papilla (Figs. 4 and 5). The culture of the bile showed bacillus coli communis. Microscopic examination of the small concretions removed with the bile from the common bile duct gave much the same picture as that found in the examination of similar particles in the bile aspirated by the duodenal tube before operation (Fig. 6).

The patient rallied well from the comparatively trifling shock of the operation, but about two weeks after operation began to vomit rather large quantities. This vomiting lasted for three days. The sutured portion of the wound healed by primary union and the bile drainage was quite clear. There was no fever after the slight postoperative rise. In spite of the cessation of vomiting and the absence of fever, the patient failed perceptibly. On November

Fig. 8.—Proposed operation for radical excision of carcinoma of papilla (after Kehr). First and second stages. Cholecystogastrostomy and posterior retrocolic gastroenterostomy. Lines of resection indicated: 1. Through choledochus. 2. and 3. Through second portion of duodenum above and below papilla. 4. Through pancreas.

Fig. 9.—Proposed operation for radical excision of carcinoma of papilla (after Kehr). Third stage. Circular resection of second portion of duodenum including papilla, with closure of choledochus and gastric stump of duodenum and pancreatoduodenostomy.

30th a right parotitis developed. The temperature rose rapidly to 105 to 106° with a pulse of 140 to 150, the patient going into a marked collapse. On December 2nd, just one month after the second

operation, the patient died, apparently from a sepsis of some sort.

The postmortem examination showed an oval carcinomatous ulceration around the papilla, involving the entire duodenal wall. The tumor was rather flat and measured about two cm. in its greatest diameter. The neoplastic infiltration had entered the head of the pancreas. The orifices of the common bilt duct and the duct of Wirsung were patent (Fig. 7). In the mesentery of the duodenum to the right of and adherent to the head of the pancreas, was a hard, whitish nodule of about the size of a large pea, apparently an invaded mesenteric lymph node. There were no other metastases. In front of the duodenum and communicating with its lumen through a small perforation in the suture line, was a large abscess containing thick, grayish pus and sloughing tissue. This localized peritonitis was undoubtedly the cause of the sepsis which was the immediate cause of death. Microscopic examination of the primary tumor showed the same pathological features as the specimens obtained at biopsy and the nodule in the mesentery of the duodenum was composed entirely of tumor tissue,of the same morphology as the primary growth.

The most striking feature in this case was the nearly total absence of jaundice except for a slight attack at the inception of the illness. After cholecystectomy even this subsided, in spite of the fact that the lesion at the papilla was still advancing. This must be accounted for by the fact that the tumor was an ulcerative type and not actually obstructive in character—as demonstrated at operation and again at the postmortem examination. The next point of interest was the relatively good condition of the patient even after the onset of the cholangitis. In most cases of carcinoma of the papilla, marked and progressive jaundice is a characteristic and early symptom, even with very small tumors, and if the pancreatic duct is involved, rapidly advancing malnutrition occurs in addition. Finally, in our case the diagnosis was made during life in the relatively early stages of the disease. In fact, after the diagnosis was definitely established, the possibility of radical excision was considered; but, of course, as matters developed, no further procedure was possible. It was greatly to be regretted that this diagnosis had not been established at the first operation when undoubtedly the tumor was already present. The patient was a young man, his condition at that time was excellent, he was practically nonicteric, he was not infected, and the gallbladder was still present to be used for anastomotic purposes. Under such satisfactory conditions and with such a comparatively insignificant lesion, a most favorable outcome of radical extirpation could have been expected.

The case certainly teaches that the possibility of the existence of carcinoma of the papilla of Vater should always be borne in mind at all gallbladder operations, especially where icterus is or has been a symptom. If there is any suspicion that this is the case, exploratory duodenotomy, with probatory excision and preferably immediate microscopic examination of the frozen section is indicated. Then, if the diagnosis is established beyond the shadow of a doubt, it should be decided as to whether radical or palliative treatment should be instituted and what method or procedure should be selected.

The recent literature on the radical treatment of carcinoma of the papilla of Vater is rather discouraging. The most complete summary within the last few years is made by Brütt (2), who has added seven cases of radical operation to the nineteen collected by Melchior (3), among which was one for benign tumor. Of the twenty-five cases of carcinoma, eleven died after operation, making a postoperative mortality of forty-four per cent. The methods used were:

1. Transduodenal extirpation of the papilla—eighteen times with seven deaths.
2. Resection of the second portion of the duodenum—four times with two deaths.
3. Retroduodenal extirpation of the distal end of the choledochus, including the papilla—three times with two deaths.
4. Excision of the papilla through the dilated choledochus by inversion—once, with operative recovery.

In 1901, William J. Mayo (4) reported the first successful transduodenal extirpation of a carcinoma of the papilla of Vater. The preliminary cholecystostomy was done to relieve the jaundice, and the growth was removed after duodenotomy, partly with the knife and partly with the cautery. Three weeks after the extirpation the biliary fistula completely closed, the stools became normal in color, the patient gained weight rapidly, and remained well for about one and a half years. Then pain and icterus developed, due to a recurrence in the pancreas and mesenteric lymph nodes. Temporary relief followed a cholecystoduodenostomy.

The two successful resections of the second portion of the duodenum which have been reported were made by Halsted (5) and Kausch (6). Both patients died of recurrence about three quarters of a year after operation. In Kausch's case the development of an infectious cholangitis also contributed to the eventually fatal outcome.

Crohn (7), in 1914, in an analysis of new growths involving the terminal bile and pancreatic ducts, made a careful study of two cases of carcinoma of the papilla of Vater including postmortem examination. He pointed out the possibility of diagnosis of the obstructive and ulcerating types of the lesion and called attention to the striking symptomatology of the two forms. He emphasized the great value of the duodenal tube as a diagnostic agent, reviewed the literature to that time, and urged the surgeon to attempt early radical operative measures.

A most interesting contribution on the subject is made by Lewis (8) who reports on the end result of a transduodenal extirpation of an adenocarcinoma of the papilla of Vater performed by Howard A. Kelly and Curtis F. Burnam of Baltimore. The patient was alive and well eight and a half years after operation.

Very recently Abell (9) has reported on three cases, in two of which palliative operations were done, and in the third radium applied by a very ingenious method. In all three cases the results were quite satisfactory. One of the cases was still alive and quite well four years and one month after the onset of definite symptoms, three and a half

years after cholecystoduodenostomy and ten months after a second operation, namely a gastroenterostomy for duodenal obstruction.

It is obvious that the most cleancut, rational surgical procedure in the sessile, infiltrating type of carcinoma is the resection of the second portion of the duodenum, including the papilla. Of course this is an operation of considerable severity, and should not be attempted in one stage even if the case is most favorable, well nourished and not jaundiced. The great surgical problem is the proper disposition of the choledochus and pancreatic ducts. We would favor a technic similar to that suggested by Kehr (10 and 11)—first the establishment of a cholecystogastrostomy, and if the patient is not jaundiced at the time, a posterior retrocolic gastroenterostomy. If the patient is jaundiced, the gastroenterostomy should be postponed until after the jaundice has subsided. The radical excision of the second portion of the duodenum, including the distal parts of the choledochus and of the duct of Wirsung with or without a portion of the head of the pancreas, could then be performed when the patient's condition had so far improved as to permit of this very severe procedure. The proximal ends of the choledochus and duodenum should be closed and the end of the duct of Wirsung or the pancreas stump invaginated into the distal portion of the duodenum. For the pancreatectomy and pancreatoduodenostomy, Coffey's (12) method could be employed. The illustrations (Figs. 8 and 9) clearly show the proposed technic. Of course this operation is not indicated in every case but would have been necessary in a case such as the one described, with the infiltration extending into the head of the pancreas. There are certain forms of the disease in which the tumor is more pedunculated, and a simpler, less dangerous procedure will suffice. After preliminary cholecystogastrostomy, gastroenterostomy or both, if necessary, such growths can be readily excised transduodenally with or without a portion of the choledochus or duodenum, but without the necessity of an actual circular resection of the gut.

Obviously radical extirpation will only be possible in those cases in which the disease is not too far advanced and in which the condition of the patient permits of a severe surgical procedure. In the others, a palliative measure, such as an anastomosis between the gallbladder and stomach, duodenum or jejunum, is not only indicated but very much worth while. If necessary a gastroenterostomy may be added. Erdmann and Heyd (13) report a case of carcinoma of the papilla, operated on by the former, in which a cholecystostomy and posterior gastroenterostomy were done and then at a second operation the cholecystojejunostomy was performed. The patient gained twenty pounds after the second operation, remained well eleven months and lived for another month, death occurring about nineteen months after the initial symptoms, fifteen months after the first and twelve months after the second operation. Judging from Abell's experience, the direct application of radium by duodenotomy is certainly worth considering. Emanation needles may be used or, according to Abell, a capsule can be anchored to the growth by a catgut suture and later withdrawn by a string through the mouth.

We do feel, however, that wherever possible, radical removal should be the procedure of choice and that our future efforts should be directed toward gaining further experience along these lines and improving the technic of the procedure. Again we wish to emphasize the point that these growths as a rule produce a prompt, definite and pathognomonic symptomatology with the great chance of early diagnosis, certainly at operation, or possibly even before with the aid of the x ray and the duodenal tube—perhaps even more favorable than in tumors of the brain or spinal cord. We also wish to reiterate the generally conceded fact that these carcinomata are usually tumors whose malignancy is of an exceptionally low order—growing very slowly and metastasizing extremely late. Although none too encouraging, the attempts at radical cure give us a ray of hope, and a few of the reports are truly inspirations toward further research. Surely, it is a sad reflection on the present, supposedly advanced state of our surgical knowledge, if we should be forced to make a confession of weakness and stand by, seemingly powerless really to help, watching the tragedy of a robust and, as in our case, a young individual, succumbing to a minute, insignificant little tumor, often not larger than a pea—a tumor which all authorities agree is of a comparatively benign nature, but whose removal, because of its peculiar situation—simply requires the solving of certain slightly more difficult technical questions than are usually presented.

The Key to the Abdomen

A. SCOTT GILLETT, F. R. C. S. E.
London

The problems encountered in the surgery of the abdomen are so important that they call for the most careful study, and demand that the surgeon shall render himself familiar with the great progress that has been made in their treatment in recent years.

I believe that the key to the entire abdominal situation lies in the recognition of the principles involved in the condition which Arbuthnot Lane called chronic intestinal stasis, the details of which he has taught for the past twenty-five years. The quicker we can free ourselves from our habitual conservative ideas, the sooner will the whole medical and lay community realize the great importance of this work. Knowledge is more often bought at the price of failure rather than by success, and it is with this object that I am referring to a series of over fifty cases of intestinal stasis which I have treated by operation. I shall briefly enumerate the measures which I have employed in my efforts to deal with the several conditions which may best be described as the sequence of chronic intestinal stasis.

SIMPLE APPENDICECTOMY FOR CHRONIC APPENDICITIS

Most surgeons will only too readily admit that a careful investigation of the results of the removal of the appendix in socalled chronic appendicitis are ignominious failures. How often after a brief interval do their patients return to them or perhaps more frequently to some other medical man, complaining of precisely the same symptoms which originally led them to seek advice and the surgeon to operate! The only result of the operation of appendicectomy in too many cases of socalled chronic appendicitis is, unfortunately, a variable number of postoperative adhesions which are a frequent source of trouble. I know from painful experience that if the whole of the intestinal tract had been carefully examined at the operation one or more bands controlling the large bowel and the end of the ileum would have been discovered and divided, and a perfect result obtained.

Appendicectomy had been previously performed in four of the cases which came under my observation for a continuance of the symptoms which existed before the removal of the appendix and upon which I operated subsequently. When I opened the abdomen I found in each of these four cases a definite first and last kink, which I divided, with the result that the patient was freed from pain and was restored to health.

It is perfectly obvious that the incisions in the right groin commonly employed by surgeons for the removal of chronic appendix are so placed and so limited in extent that it is quite impossible to make a thorough examination of the intestines through them, and in consequence their use completes the tragedy so far as the patient is concerned. If a median or paramedian incision of sufficient length had been employed, the true origin of the trouble would have been discovered by the surgeon only, however, if he were familiar with the structural changes which exist in stasis. The primary and most important obstruction is situated in the end of the iliac colon, where it forms what is suitably described as the first and last kink and other secondary kinks might also be present. After reviewing the whole series of cases the continued employment of what we may call, perhaps, the cosmetic incision would be comic if it were not almost criminal.

CECOPLICATION AND CECOPEXY

The next effort which I made was to perform one or both of these two operations which were popular at the time, relying upon what I now recognize to be an incorrect supposition that the cause of stasis existed either in the pendulous or baggy cecum or a hypermobile section of the colon. This method of operation originated with Rovsing of Copenhagen and he had many followers in England and abroad. That this conception was entirely wrong was proved conclusively by the results in a series of thirty-two cases in which I had employed this procedure. The successes I obtained were negligible. I may say that I have seen many cases which have been operated on by other surgeons with no better result, so that my failure is not unique. The reason was that the real cause was neither searched for nor remedied: indeed, in the light of Arbuthnot Lane's work, everything possible had been done to aggravate rather than alleviate the static condition. Whereas the patient originally possessed one or more intestinal kinks, he had superimposed on him many new adhesions of postoperative origin. The only thing he lost was his check.

COLECTOMY

I performed this operation in five instances. One of the disadvantages of this operation is shock which in some few cases may be considerable and persistent. This may, however, be minimized by the abundant injection of normal saline into the axillæ. This should be commenced as soon as the patient is sufficiently insensitive not to feel the prick of the needles, and it should be continued during the whole operation. Perhaps the complication which causes the surgeon and patient most trouble is the formation of inflammatory adhesions, as is all other intra-abdominal operations, evidence of which may not appear for many years. Three of the five cases did well, one gave a very poor result and one patient died. The explanation of the failures lay possibly in faulty technic and a want of familiarity with the operation. Colectomy is only called for where there is extensive ulceration or extreme dilatation of the large bowel, or in what is called megacolon, or where the patient has not been restored to health by the division of the kinks. I believe I am correct in saying that the pioneer himself employs it far less frequently than before, possibly because he does not see the same serious cases as he did when he was on the active staff of Guy's. In a large percentage of cases the operation for freeing the kink or kinks affords a perfectly satisfactory result and with the minimum amount of risk of life. The liberation of

the bowel from acquired adhesions calls for the greatest care both in the division and separation of the bands from the mesentery and in the covering of raw surfaces with perfect accuracy. My experience in quite a large number of abdominal operations of various sorts shows in the clearest manner possible that it is only by a recognition of the mechanical changes that take place in the gastrointestinal tract in chronic intestinal stasis and of the means by which their change can be rectified that we shall be able to deal with them effectively. I cannot illustrate this better than by referring to one of the most painful and serious results of intestinal autointoxication. A boy, aged fifteen years, who lived upon a farm, had suffered from major epileptic seizures early in life, their number varying from two to three a week. Clinical and radiographic examinations elicited a well marked first and last kink. I freed the kink by operation seven and a half months ago. The day following the operation the boy had a fit. Three days later he had another of minor degree. Four days later he presented what may be best termed an attempted fit; since then he has been absolutely free. I know of several other similar cases in which the same happy result was obtained by this procedure.

It is impossible to see the results of this operation without being astonished by the extraordinary improvements in the mental and physical condition of the patient and the rapid elimination of the chronic and severe toxemia.

An intelligent recognition and practice of these principles must inevitably confer an inestimable benefit upon a toxic humanity.

Retrorectal Tumor*

HARRY A. DUNCAN, M.D., F.A.C.S.,
Philadelphia

In November, 1921, Miss P. S., aged twenty years, came to me complaining of pain at the end of the spine and because of this, inability to sit down. This condition first appeared two months ago. Her previous health had been good. There had always been a tendency to constipation which had become worse during the last two months. She stated that an enema gave better results than a physic. During these two months she lost twenty pounds in weight. A slight temperature of 99° to 100° had manifested itself during the last week. Her menses had always been regular but recently there had been a slight vaginal discharge. A moderate leucocytosis was the only abnormal blood finding.

On examination there was found bulging of the perineum—exactly the picture seen during the stage of labor when the descending head causes the perineum to bulge. The vagina admitted two fingers but was greatly encroached upon by a smooth semi-fluctuating mass the size of a fetal head. It was difficult to palpate the uterus but nothing abnormal could be found. Digital examination of the rectum revealed nothing abnormal with the rectum, but it was crowded forward against the posterior wall of the vagina by the mass. This mass lay between the posterior wall of the rectum and the coccyx and sacrum and was apparently attached to the left side of the sacrum. There was no great tenderness or any other sign of inflammation. The mass was evidently a new growth. I had never seen anything like it and found little to enlighten me in the usual textbooks on surgery. Dr. DaCosta stated that he had helped Dr. Keen remove such a growth and I became convinced that it was a rare condition until I searched the works on pathology where I found a great deal on the embryology of the caudal end of the human embryo "gone wrong" and congenital tumors of this region.

At operation an incision was made between the anus and the tip of the coccyx extending to the right. A thick walled cyst was enucleated with the finger up to the point of attachment on the left side of the sacrum. The attempt to free the growth from this point caused it to rupture. The cyst was filled with a thick sebaceous fluid containing many flakes. The cavity was packed with gauze which was gradually removed during the next three days. The recovery was without incident and two years after the operation the patient reports her health as excellent with no recurrence of the growth.

Dr. J. H. Clark furnished the following notes on the pathology of the tumor:

"The wall was composed of fibrous connective tissue of varying thickness, lined on the inside with two types of epithelium, the greater portion being squamous epithelium of varying depth; while other areas showed a high columnar mucus secreting epithelium as shown by the presence of numerous goblet cells. The wall of the cyst showed in many places thickened bloodvessels and evidences of fibroblastic proliferation. At one area just beneath the outer wall of the cyst was tissue resembling immature nervous tissue, consisting of small poorly differentiated cells and numerous large irregularly triangular cells with a large nucleus and definite nucleolus. The tissue as a whole showed evidences of a chronic inflammatory process. No tubercle bacilli were found in the material from the cyst either in direct smears or after treatment with antiformin. Diagnosis, teratoma."

According to Ewing the embryonal structures giving rise to sacrococcygeal tumors are chiefly the fovea coccygea, and the coccygeal vestiges of the neural canal, the neurenteric canal, the postanal gut, and the proctodeal membrane. The abnormalities or tumors resulting are:

Dermoids, simple or complex.—Simple dermoid cysts—as pilonidal cysts—occur frequently in the midline posteriorly. Suppurative changes may cause them to be mistaken for tuberculosis of the sacrum.

*Read before the Samaritan Hospital Medical Society, February 4, 1924.

Complex dermoids contain bones and teeth as well as hair.

Teratoid tumors.—These are solid and cystic at the lower end of the spinal column in front of the sacrum and coccyx. The spinal dura is not involved as a rule while tumors on the dorsal surface of the sacrum usually involve the dura and are attached to the bone.

Teratomata.—These tumors contain definite organs not referable to neighboring structures—such as scapula, bronchi, spleen, kidney, brain. They are usually situated posteriorly to the sacrum. Sacral teratomata are often associated with spina bifida. Malignant changes may take place in teratomata.

Fetal implantations.—These vary from the monster to the more highly developed types, as the Siamese twins.

ETIOLOGY

No definite cause can be assigned as accounting for any of these tumors. The monster or parasitic fetus is probably bigerminal in origin. Such conditions may result from the partial fusion of two originally separate embryos, derived from one ovum, or from the incomplete splitting of one original embryo. When two embryos are joined together and one goes on to complete development while only certain parts of its companion continue to grow, the result is a parasitic fetus or monster. Ewing seems to dissent from this view when he says: "The origin of the fetal implantation may in certain cases be attributed to a second embryo which in some way becomes attached to the tissues of its host, the autosite. This mode of origin is, however, probably the rarest of events, for the evidence of comparative embryology points to the process of budding as the most probable course of parasitic implantations, especially when the parasites are multiple and their development markedly imperfect." The simple tumors exhibiting tissues or organs similar to that found in the immediate neighborhood are probably monogerminal in origin, due to budding processes or impurities in specific germ layers.

According to Parin presacral tumors are less frequent than those situated on the posterior border of the sacrum and coccyx. They are distinct from the latter from the clinical point of view and their operative removal presents greater difficulties. Kiderlen in 1899 assembled from the literature 122 cases in which the tumor was located entirely or partially in the presacral region. In twenty-five of the cases, however, the growth was a dermoid cyst. Presacral tumors, when situated in the typical position, force the anus forward and the coccyx and sacrum backwards and often extend into the cavity of the large pelvis.

Parin was able to find fifteen cases of congenital tumors, located partially or entirely in front of the sacrum, and reported in the literature of a ten year period (1900-1909). He agrees with the usual view that it is impossible to distinguish between monogerminal and bigerminal origin. Six instances are cited in which mixed tumors in the sacral region became malignant and formed metastases.

Graffa collected from the literature several cases in which carcinoma arose on the base of dermoids, and reports the following case of retrorectal teratoid tumor with adenocarcinomatous degeneration:

Case.—A nullipara, thirty-four years of age, with negative family and personal history, began to feel pain in the right gluteal region. The sensation was at first slight, but gradually increased in severity and at times there was itching at the anus. Evacuation of the bowels caused no discomfort. Menses were regular. At examination there was found a tumor as large as a child's head, situated between the rectum and the sacrum. It adhered to the sacrum but showed only a loose connection with the rectum. The rectum itself was intact. A rightsided parasacral incision, beginning at the anus and mounting upward along the border of the sacrum, was made and the tumor loosened, in part bluntly and in part with scissors. The adhesions to the sacrum were relatively loose so that manual separation could be effected comfortably, but in loosening the second half of the tumor the capsule tore and a good half liter of typical, light green pure dermoid pulp, unmixed with other elements such as hair or teeth, was discharged. The patient was released four weeks later as cured, but six weeks after release there were signs of emaciation and violent pains in the cicatrix. Three months after operation the patient died of recurrent adenocarcinoma.

Honigmann reports the spontaneous expulsion of a presacral tumor per anum in a woman forty-three years of age who had suffered from tenesmus and pain, especially in evacuation and in whom a diagnosis of simple proctitis had been made.

Stoner in a paper on "The Significance of Sacrococcygeal Dermoids in Relation to Rectal Disease," says infected dermoids lying in front of the sacrum may discharge into the rectum or open finally near the anal border on the outside. All rectal fistulæ are the result of abscess formation, some of which undoubtedly originate from dermoid cysts in the sacrococcygeal region.

TREATMENT

Adhesions often render operation difficult. Leriche (cited by Kirmisson, 1899) injured the rectum and caused a fecal fistula which healed with great difficulty. In the von Bergmann case (1884) a sacral tumor was separated from the posterior wall of the rectum and the given portion of the rectal wall became gangrenous. Perforation and death resulted. In the Helferich case a tear 1.5 cm. long developed in the posterior wall of the rectum after removal of the tumor. Two sutures failed. Thermocauterization was done, but six months after the operation the fistula still contained feces.

There is always a possibility of invading the abdominal cavity or the central canal of the spinal cord. Operative complications are particularly dangerous with children where it is difficult to avoid infection from the anus. Englemann reports a case in which the peritoneum was torn for a distance of one cm. on a three days' old child who died of shock the following day. In another case the same operator found the coccyx invading the tumor and was obliged to resect the bone. During the efforts to loosen the growth the wound filled with fluid from the central canal of the cord and on the following day there were symptoms of paralysis.

Cystic teratoma can be confused with anterior spina bifida and errors of this sort are another source

of fatal consequences. Since the growth is not always a compact mass, parts are sometimes left *in situ* and these give rise to fistulæ. In Parin's case two operations were necessary. A fistula remained after the first intervention and a portion of the tumor was found behind the rectum.

The fear of peritoneal injury has sometimes caused surgeons to refrain from total extirpation. In cases reported by Heidelberg and Petrow the tumors were lost in the depths of the pelvis and total extirpation had to be abandoned, but in both cases the fistula healed eventually. The removal of the coccyx helps considerably in gaining access to the tumor. Tillman warns against resecting the sacrum. Polloson performed laparotomy and thus removed a presacral tumor whose principal mass extended into the large pelvis.

According to the Calbet statistics (1893) there were twenty-five recoveries among fifty-three operations for congenital sacral tumors, nine cases of improvement, with fistulas in five of the nine, and sixteen deaths. In Kiderlen's statistics, covering 122 cases of congenital tumors situated entirely or partly in front of the sacrum (including twenty-five dermoids cysts), there were sixty-six cases treated by operation, eleven of which were fatal. Calbet states that there were eleven recoveries and ten deaths when the operation was performed in the first half of the first year of life, and four recoveries and four deaths when the intervention fell in the second half of the first year. According to Kiderlen's statistics there were eight recoveries and seven deaths (including one death from carbolic poisoning) in fifteen cases in which the patients were operated upon the first half year. Of two patients operated upon in the second half of the first year, one died and one recovered. Of forty-two patients operated upon after the first year, there were recoveries in thirty-three of the cases, incomplete recovery with fistula in six cases, and three deaths. In the sixteen cases of teratomata assembled by Parin with partial or entire presacral location, there were twelve recoveries and three deaths. If we exclude cases antedating 1875, we find that in congenital presacral tumors removed after the first year of life, only one death is recorded. In a case reported by Hildebrand the patient was forty-three years and in one by Salitschew he was fifty-four years old.

In general, prognosis depends on the age of the patient and the relation of the tumor to its surroundings.

The Importance of Appendoröntgenography in Its Relation to Surgical Intervention

JOSEPH FRIEDMAN, M.D.

New York

Of all the means employed for the differentiation of abdominal lesions no aid leads nearer to a more positive conclusion than properly conducted röntgenography, particularly as to pathological conditions or the indications for surgical intervention.

The chronic irritative appendix, usually termed chronic appendix, presents various pictures upon the röntgenogram, but among these great stress should be laid upon the so formed sluggish appendix which has proved to be of far more importance than is usually considered. In the röntgenological examination of the appendix careful search of the urinary tract is necessary, particularly of the right side, in order to exclude calculi; of course affections of the urinary tract need not exclude those of the digestive organs.

In carefully examining the alimentary tract the duodenum must be observed for either ulcers or other irregularities. One should be careful not to conclude that adhesions exist until the parts have been taken in various positions, as grave errors may be made through hasty conclusions made from a few films. Examinations at various angles and positions are needed to decide with any degree of probability upon the presence of adhesions and to differentiate them from spastic constrictions, a condition occurring not infrequently.

The opaque meal used to examine the intestinal tract must be observed in its course by means of the röntgenoscope, during which progress the appendix must be studied in its various phases.

The normal appendix is represented upon the röntgenogram by a fine linear or segmented shadow projecting from the lower and inner portion of the cecum and varying considerably in its length, thickness and direction. Its observation requires practice and close scrutiny and may be best studied twenty-four hours after the opaque meal has been taken. Although at times the appendix can be seen before that time, in some instances a longer period is required.

The complete examination of the appendix usually takes from three to six days or even longer, dependent upon peristalsis; but observation of its con-

tents should continue until the lower cecum and the appendix are free from the opaque mass, as upon such observations the diagnosis may depend.

The appendix in the retrocecal position is frequently held obscure except when taken in a right lateral oblique position; of course it becomes visible if the opaque mass is retained after the opacity has left the cecum.

When the opaque mass of the appendix disappears with that of the lower cecum or even a few hours later, the appendix may be considered normal. Its retention for one or two days may be considered of little moment but if the opacity remains in the appendix for a longer period one must watch for abnormal conditions and observe position, shape, adhesions or kinks; also peristalsis, stasis, and other conditions.

Retention of the opaque mass for more than three days is evidence of poor drainage and suggests what may be termed a sluggish appendix, the time of retention which might be termed the time of opacity, indicating the degree.

It might be of interest to give brief outlines of several points of importance connected with my observations in studying röntgenographically a number of abdominal affections. Most of these patients suffered from pain varying in location in the abdomen and whenever at the seat of pain no other cause could be demonstrated by any form of examination the appendix was watched as to the time the opaque meal was retained; others had been constipated and taken laxatives for years. Among them were a number upon whom various operations had been performed, while other patients examined were supposed to have biliary, renal, ureteral ailments or diseases of the digestive organs.

Some patients suffered from recurring painful attacks, though not always in the region of the appendix, which disappeared and never returned after the removal of a sluggish appendix.

It is important to note that the presence of a chronic irritative appendix must be strongly suspected when the appendix contains the opaque mass after thorough catharsis; or the visual absence of the appendix, the proper technic having been used, without a history of a previous appendectomy, indicates that the mass did not enter the appendix because of obliterative processes. These forms of appendices must always be considered pathological.

From this experience it seems reasonable to say that every appendix of more than five days' opacity after a laxative test proves a sluggish appendix and suggests removal and the findings in these operations always corroborated the diagnosis.

Chronic irritative appendix must be röntgenographically differentiated from: 1, Renal and ureteral calculi, right sided hydronephrosis; 2, hardened concretions; 3, enteroliths; 4, calcified glands; 5, tuberculosis of cecum; 6, carcinoma of cecum; 7, some form of tuberculous mesenteric glands; 8, duodenal ulcer; 9, gallstones; 10, adhesions about the cecum and upper portion of ascending colon from prior inflammation.

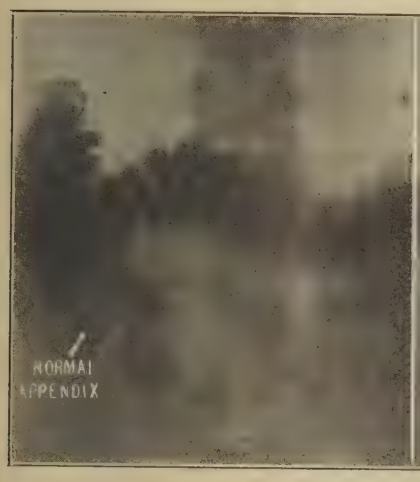

FIG. 1.—Lower cecum and appendix empty in twenty-four hours.

FIG. 2.—Showing hardened concretions in the appendix.

FIG. 3.—Lower cecum and appendix, 120 hours after barium.

CONCLUSIONS

A chronic appendix may be shown by:

1. Visual absence of appendix.
2. Concretions.
3. Local area of tenderness in the course of the appendix shown on röntgenoscopic examination, providing other irritative centres in that region have been ruled out.
4. Retention of the barium meal in the lumen of the appendix for several days after the lower cecum is empty despite a laxative.
5. Irregularities in the lumen, particularly a bulbous tip.
6. Adhesions about the cecum and the terminal ileum, indicating inflammatory process.

Hematocele Following Splenectomy Demonstrated by Pneumocolon Röntgen Examination

HERMAN B. PHILIPS, M.D.
New York

The following case history warrants a report, in view of the unusual character of the pathological condition and of the method employed in making the diagnosis:

Case.—J. M., aged four, referred by Dr. E. A. Rosenberg, was playing in the street, December 22, 1920, when he was hit by an automobile and sustained a severe blow over the upper abdomen. He went into shock immediately with signs of internal hemorrhage and peritoneal irritation. He was taken to a large city hospital and operated upon immediately. The laparotomy revealed a ruptured spleen, which was removed in the usual manner. He remained in the hospital for one month making a smooth uneventful recovery.

The night that he left the hospital, he was taken with severe pains in the upper abdomen and became prostrated, extremely pale with a rapid pulse, and his condition was almost as severe as immediately after the accident. It was at this time that the patient came under the observation of the referring physician.

Physical examination was not conclusive in establishing the source of trouble and he was sent back to the hospital for observation, possibly operation. He remained in the hospital for two days, it was decided not to operate, and he left the hospital slightly improved.

Fig. 1.—Air in colon forms a contrasting background which completely outlines the tumor.

For one and a half months his condition progressed unfavorably. The abdomen became more swollen and gradually a large tumor mass became palpable filling the abdomen and pelvis. Different methods of physical examination failed to determine what the character of the condition might be. The outline of the tumor mass could not be determined, owing to the extreme tension throughout the entire abdomen. He was referred at this time for x ray examination, which showed a diffuse homogeneous shadow throughout the entire abdomen and pelvis. X ray examination was then repeated after inflation of the colon, after the method described by the author (1), with most satisfactory results.

A discrete spheroidal tumor mass was found to occupy the upper left two thirds of the abdomen, which when studied under the fluoroscope and by stereoscopic röntgenograms appeared to have a distinct attachment to the splenic region, and in view of the history a diagnosis was submitted of a probable hematocele arising from the slowly bleeding stump of the splenic artery. The air in the colon formed a contrasting background which permitted a clear visualization of the entire margin of the tumor. (Fig. 1.)

The patient was now referred back to the hospital for operation and the operative findings included the removal of a hematocele arising from the stumps of the splenic vessels. The patient made an uneventful recovery after removal of this large tumor, two years ago, and up to the present time feels entirely well, without any abdominal symptoms whatsoever.

COMMENTS

Hematoceles arising from the splenic artery are extremely rare. A thorough search through current and recent medical literature fails to find a record of a similar condition.

X ray after the inflation of the colon has a limited but an extremely useful field of application. It gives uniformly satisfactory results, when the tumors are large, but is not as useful as pneumoperitoneum in detecting small tumors, adhesions, and other conditions. On the other hand, its simplicity, freedom from risk and discomfort and the avoidance of any operating room details, makes it a procedure easily applied and extremely advantageous in a great number of instances.

Nervous and Mental Phenomena Following Chronic Intoxication with Valerian

ALFRED GORDON, M.D.,
Philadelphia

Valerian is one of the most active antispasmodic remedies. Every one of its preparations has similar physiological reactions although they differ in degree and intensity. The characteristics of the reactions consist at first of stimulation of the brain and medulla. This phase, which is brief, is promptly followed by a more or less prolonged period of fatigue, apathy, and a paretic state. The modifications in the function of the motor apparatus also in the reflectivity are apparently of central origin and not of peripheral, as the first impression may be. The sympathetic nervous system is apparently also involved, since the vasomotricity is equally influenced; the vasoconstrictors are manifestly affected, as the arterial tension is elevated. On the other hand, when stronger doses of valerian are taken, hypotension is observed.

Not only the circulatory but also the respiratory apparatus is influenced by valerian or by its derivatives. The number of respiratory movements is decidedly augmented and again probably through a cerebromedullary mechanism.

Physiological as well as experimental investigations show conclusively that the chief effect of valerian lies in the antagonism to convulsive or excitant states. L. Branton, for example, observed that valerian arrested the spasmodic action of small doses of strychnine. All excited states of the nervous system being manifested in cerebromedullary phenomena in the domain of the circulatory, respiratory or digestive apparatus become diminished, greatly modified or removed by administration of valerian. In Grisar's experiments there was a diminution of reflexes, somnolence, a paretic state and general depression of the nervous system (1). Sikorska's (2) experiments show that small doses are an excitant of the motor cortex; large doses produce depression, and from all doses there is a diminished resistance to fatigue.

In a general manner valerian is to be considered as an excitant terminating in depression or perversion of motor functions. Féré (3) arrived at the same conclusion. Finally in more recent investigations H. Boruttan (4) demonstrated that under the influence of valerian dogs become quiet and react little to external stimuli; they remain in a sitting position with open eyes, and their reflex irritability is diminished. Furthermore when larger amounts of the drug are given by injecting it into the lymphatic channels, prolonged paralysis of the central nervous system is observed.

In the literature at my disposal, with one single exception, no mention is made of symptoms referable to the function of the cerebellum under the influence of valerian. E. Durand in his book on valerian published in 1921 is the only author who in his experiments with valerian on mice and guineapigs observed manifestations, not only of disturbed cerebrum and medulla, but also of the cerebellum, namely, rotation around the axis and loss of equilibrium.

I also failed to find in the literature records concerning the prolonged or chronic use of valerian. The majority of clinical and experimental investigations on the subject are concerned exclusively with immediate effects of the drug, but not with remote reactions after the patient has been taking it for a continuous period of time.

In view of the fact that valerian is useful as a sedative medication in hysterical and other functional disorders of the nervous system, also as a rapidly active stimulant in certain low states which occur in acute febrile diseases, it appears interesting and instructive to put on record the history of a case which presents, in addition to the well known characteristics, the two special features not mentioned in the literature, namely, the consequence of a chronic intoxication with valerian and the cerebellar manifestations.

The preparation used in this case was tincture of valerian. At this juncture it may not be superfluous to mention that the cerebromedullocerebellar as well as the mental phenomena, in the opinion of the sceptical observer, may have been due to the alcoholic content, with which tinctures are usually prepared. To refute this possibility it is well to bear in mind the recent experimental work of Macht and Ting (5). They have shown that the effect of

valerian is not due to inhalation of alcohol contained in the tincture of valerian, because controls made with the same quantities of ethyl alcohol alone failed to produce the symptoms caused by the drug.

Case.—Mrs. A. H., aged thirty-five, following a difficult and protracted labor commenced to use tincture of valerian for insomnia. At first she was given half a dram. Gradually, without asking the advice of her physician, she increased each individual dose. Having succeeded in obtaining the drug without prescriptions, she continued using it daily.

At the time she came under my observation I was informed that the patient had been using the drug to the exclusion of any other medication during a period of eighteen months. Her daily ration was one ounce which was taken in teaspoonful doses several times a day. Prior to the date when she commenced the use of the drug she was in excellent condition. The somatic recovery from the difficult labor was also complete. There was no history suggesting lues. She had three healthy children. The Wassermann test of her blood, as well as of her husband's, taken twice, was negative. The family history was also normal. The patient prior to or during her present illness never used alcoholic beverages. Her mental condition was formerly good. A complete blood examination showed a somewhat low hemoglobin content (75); red blood corpuscles 4,000,000; the white corpuscles 10,000. No abnormalities were found in the blood cells. The slight anemia present was not sufficiently pronounced to cause the symptoms referable to the central nervous system. Uranalysis showed: specific gravity 1030, traces of albumin, no sugar, a few hyaline casts and cylindroids.

The patient's condition was as follows: There was a marked mental hebetude; an inability to carry out correctly orders given: at first she tried to comprehend the questions asked, then she stared, hesitated, attempted to do what she was told, interrupted her attempts, commenced it over again and finally acted in a reverse manner. For example, when told to stand up, she extended her legs; when told to extend the arms, she flexed them. When told to protrude her tongue, she closed her mouth tightly. When told to write, she did not know how to go about it. When a penholder was placed in her hand, she attempted to write with the opposite end of it. Objects shown her she misinterpreted, and when reminded of the correct names, she hesitated before repeating them and soon forgot them. When left to herself, she walked in the wrong direction even to the point of danger; she was likely to walk towards an empty space. She would attempt to handle burning objects if not prevented from doing so. She often talked to herself in a most unintelligible manner. She had to be fed. She was extremely unclean, handled the excretions, urinated wherever she happened to be. She showed no delusions, but a hallucinatory state was present, as frequently she was found talking in an animated manner with her eyes directed towards the ceiling and moving her hands in the same direction. At times she became delirious, at others stuporous, or mute; she was totally oblivious to surroundings.

Somatic phenomena. — The gait was decidedly ataxic, such as is seen in cerebellar lesions. There was a tendency to fall backwards: the trunk did not follow the legs (asynergia) and at the same time a zigzag movement of the body was evident: she walked from side to side. She dragged her legs, scraped the floor in walking. It was a great effort for her to go up the stairs: she was obliged to hold on to the bannister with one hand and with the other she held on firmly to another person; then she tried to raise her foot, but the toes invariably struck the woodwork before the foot was placed on the next step. Station with open and closed eyes was impossible, she immediately fell backwards.

The tonicity of the lower limbs was decidedly lowered. Their flaccidity was marked. Although voluntary movements were possible, nevertheless they were extremely slow. Passive movements were carried out with great facility in view of the hypotonia. The muscular power and tonicity in the upper extremities were identical with those of the lower ones. The patellar tendon reflexes were markedly diminished. The same was observed with the tendon Achilles reflex. As to the plantar reflex it was variable: sometimes there was no response at all to stimulation of the sole, sometimes there was a mild extension. The same results were obtained with other methods (Oppenheim, Chadwick and Gordon). There was some ataxia in the upper extremities observed with both pointing and the finger to nose tests. In the first test the patient's finger never reached the object placed before her, but invariably fell externally and at a considerable distance from it, more with the right than with the left hand. In the finger to nose test the index reached the point of destination only after several excursions in all directions. The tendon reflexes of the upper extremities were obtainable but with great difficulty; the amplitude of the arms on testing was notably small. Adiadochocinesia was distinct in the right hand; in the rapid pronation and supination movements this hand was manifestly lagging and did not keep pace with the left hand. General sensibility to all forms was diminished. Tests for special sensations could not satisfactorily be carried out in view of the patient's disturbed mentality. The eyegrounds with the exception of a slight congestion of the retinal bloodvessels were normal. The ocular muscles functionated normally, but there was, however, a lateral nystagmus when the eyes turned to the right. The speech did not show the disturbances which are usually observed in organic lesions of the brain. There was no motor aphasia or anarthria, but the words were uttered very slowly and at times they could not be understood fully, the labial letters especially not being clear. As to sensory aphasia, it could not be determined because of the incoherent mental state.

The course of subsequent events in the present case was as follows: By gradually decreasing the quantity of valerian, by prolonged rest in bed, appropriate dietetic and hygienic measures, finally by complete withdrawal of the drug, considerable improvement was obtained. At the time of writing these notes the cerebral and cerebellar manifestations have totally disappeared. However there is

still present a state of asthenia which has not yet been removed.

To sum up the striking manifestations of the present case, we find a combination of mental and nervous phenomena such as are frequently observed in classical psychoses and in organic diseases of the nervous system. As to the former, there are present many essential elements of a confusional psychosis, which is frequently observed in postinfectious processes of any origin or in toxic states from acute or chronic absorption of organic or inorganic chemical elements. The absorbing interest in this case lies in the cerebellar manifestations which are ordinarily encountered in tumors, vascular lesions or lues of the cerebellum.

The morbidity of this organ was so striking at first glance that no other possibility suggested itself. Further examination and observation pointed more and more strongly that a toxic state could simulate any gross lesion of the central nervous system. It is well known that syphilis could at any stage present symptoms of cerebral, medullary, cerebellar and peripheral character. Recently a young married woman, wife of a physician, presented typical phenomena of a cerebellar nature all confined to one side. All the characteristic symptoms were present with the exception of papillary edema. The patient was treated with antiluetic remedies and made a complete recovery.

In cases of acute or chronic morphine intoxication, changes in the motor and sensory apparatus, also in reflexes, are commonly observed. In a recent case of heroine intoxication there were present symptoms referable to cortical irritation with epileptiform convulsions as a consequence (6).

Valerian is an antispasmodic like morphine and heroine and like them may be useful in many instances of nervous irritability. On the other hand, like them, it may become damaging directly to the central nervous system when a state of valerian toxicity develops. Experimental data related above go parallel with clinical observation.

The pernicious effect produced by a prolonged ingestion of valerianate preparations on the economy in general and on the central nervous system in particular, finally the occurrence of cerebellar phenomena which with one exception have never been mentioned by experimental investigators—all these reasons warranted the writer placing this case on record.

Diet in the Causation of Epilepsy

EDWARD A. TRACY, M.D.,
Boston

Before bringing to the attention of the reader some observations that show a causative relation between diet and genuine epilepsy, I shall give a very brief résumé of important findings in an investigation of this disease that demonstrate it to be a diseased condition of the vasomotor nerve fibres, indeed a true neuritis. This research was published (1) and the facts contained therein of the diseased condition of the sympathetic fibres (vasoconstrictors), manifested by the abnormal reactions of these fibres to measured stimuli, and by the presence of chronic vasoconstriction spots (white spots in the skin of epileptics, due to diseased overactivity of the vasoconstriction fibres involved in the spots) have not been questioned. Nor can these facts successfully be disputed, for they are objective signs, readily demonstrable on the epileptic patient. These objective signs are so characteristic that an accurate diagnosis of the disease has been made frequently by noting their presence. It behooves the psychiatry fraternity to become acquainted with the phenomena, as the following case in point illustrates.

Fannie, a girl of sixteen, was having queer attacks: she would suddenly run to the sink for a drink, and would sometimes fall before getting there. She was taken to the Massachusetts General Hospital, where no diagnosis was made; she was under treatment at the Boston City Hospital for a while, the neurologist there stating to her older sister that he "suspected" epilepsy. Fannie was then taken to a psychiatrist in Boston, who is regarded as an authority in Court practice; he examined the girl and informed her sister that Fannie was normal. Three weeks after this examination, Fannie was brought to me, and I, finding present in her the objective signs mentioned above, made a positive diagnosis of epilepsy, and so informed the sister. This diagnosis was confirmed by the after history of the case—the outbreak of many *grand mal* attacks in the course of the year following.

Other important findings made in this research are a hypertonia of the sympathetic fibres in the incipient stage of the disease (associated with the symptoms fainting spells, sudden pallors, sudden weaknesses, attacks of dizziness, sudden lapses of consciousness, etc.), a hypertonia that the drug *oenanthe crocata* was found to quell,—thus determining this drug to be a sympathetic paralyzant. The hypertonia and the symptoms mentioned gradually disappear under oenanthe medication.

The research work on incipient epilepsy was reported at the Boston meeting (1921) of the American Medical Association (2) and published.

An important finding made in chronic *grand mal*

with frequent convulsions is that of a calcium deficiency—demonstrated by x ray investigation. This finding clearly indicates the need of calcium medication (or feeding) in epilepsy, and explains the benefit often witnessed on fulfilling this indication.

Having touched briefly upon a research that has gotten at facts that disclose the nature of the disease —in the beginning a hypertonia of vasomotor fibres that unchecked goes on to a condition in which there is a manifest calcium deficiency, and a manifest cortical hyperirritability, I shall proceed to relate some observations relevant to the title of this article.

ETIOLOGY OF EPILEPSY

In the etiology of epilepsy, there is constantly found in the history of most cases the infectious diseases of childhood, especially scarlet fever, whooping cough, and measles. Fright is important in the etiology: a carefully investigated case of epilepsy arising from a severe fright in a healthy child with a good heredity and no previous illness was reported by me (3). Grief and anxiety are causative of the disease in adults. Direct heredity is rarely met with and I am not prepared to admit that the diseased condition of the vasomotor fibres constituting epilepsy is congenital except in very rare cases.

This diseased condition of the vasomotor fibres (it is a real neuritis of these fibres) may well be caused by the sepsis accompanying the infectious diseases, and it may be caused by a disturbance of the nutrition of those fibres through lack of essential nutritive elements. Comparatively recent research by various workers in the field has shown that the vitamines are essential for normal nutrition. The writer had the good fortune of being privileged to observe the results of experimental work on diet in animal feeding conducted in the Forsyth Research Laboratory, Boston, by Dr. Percy Howe, assistant professor of dental research, Harvard University. In the monkey, deprivation solely of normal vitamine contents of the food has produced epilepsy; and for more than a year I had under observation a monkey with idiopathic epilepsy, which at its inception was associated with tetany, the condition being attributed to such vitamine deprivation.

Until I observed this case, the etiology of certain cases of epilepsy met with in practice appeared to me quite obscure. For an example, I will briefly relate one of them. Nestor, a boy eight years old, had had *grand* and *petit mal* since the age of six months. Heredity was good and birth was normal. No disease present previous to outbreak of convulsions at six months. Cut his first teeth between six and seven months. He was weaned at three months and fed on a proprietary food, and no orange juice was given until six months of age. At six months there was an outburst of convulsions, which continued to recur for several years. In the case just outlined, we can fairly attribute the epilepsy to the only feature in which the child's bringing up differed from that of the other children in the family—his early weaning and artificial feeding, so that a defective diet can be claimed as the cause of the epilepsy. Inasmuch as the first teeth came between six and seven months, it would seem that it was not a lack of assimilable calcium content that caused the epilepsy. The observation of the monkey with epilepsy caused by a vitamine deprivation (the calcium content of the diet was normal) renders me inclined to attribute this boy's epilepsy to vitamine deficiency—which he would have escaped had he been kept on his natural diet, his mother's milk.

I need but allude to the nervous disease beriberi —caused by lack of vitamine B, to prove the importance of the vitamines in nerve nutrition. I have said that epilepsy is a vasomotor neuritis. The facts disclosed in the investigation reported (1) including abnormal vasomotor reactions, indicating hypertonia, hypotonia, and absence of the vasomotor reflexes in the bloodvessels of the skin, together with the presence of chronic white spots on the skin of epileptics (caused by a hypertonia of the vasoconstrictors involved in the spots) are best explained by the pathological conditions of the vasomotor fibres discovered by Echeverria, and carefully investigated by him microscopically, and fully described in his work (4).

With this knowledge that epilepsy is a disease of the vasomotor system, at first probably functional, and manifested by a hypertonia, quellable by oenanthe, and progressing, untreated, into a neuritis with pathological changes, and associated with a calcium deficiency of the body tissues,—the indications for correct treatment are certainly clear. The nourishment of the diseased nerve fibres and cells (the cortex cells are affected in *grand mal*) is clearly called for. And this indication, in view of what has been mentioned in relation to vitamine deficiency and the production of nervous diseases, calls for a careful provision of vitamines in the diet of the epileptic patient.

CONCLUSIONS

The results attained from the careful treatment of epilepsy in accordance with the findings briefly sketched in this article, permit the following general conclusion: Genuine epilepsy is a curable disease. In the incipient stage, and even after the appearance of convulsions, the cure is easy; in the chronic case the cure is difficult. If in the progress of the disease nerve fibres essential to normal brain function have been destroyed—the case is incurable. But who will determine that in a given case such destruction of fibres is present, especially in a case without marked mental impairment? There is hope therefore in chronic cases, and persistent treatment to restore normality to the tissues and organs of the body by appropriate diet and medicine is followed with results that appear miraculous when compared with the results of the treatment generally in vogue, —i. e., the mere suppression by powerful drugs of the convulsions, with no attempt to understand the basic pathogeny of the disease or to meet the indications this pathogeny points out for the restoration of the diseased vasomotor system to neural health by suitable nutrition and medication.

Allergy as a Factor in the Etiology of Idiopathic Epilepsy*

Preliminary Contribution

E. BOSWORTH McCREADY, M.D., F.A.C.P.,
and HENRY M. RAY, M.D.,
Pittsburgh, Pa.

After centuries of study the explanation of the convulsive phenomena making up the symptom complex commonly designated as idiopathic epilepsy remains unsatisfactory and uncertain.

None of the current theories such as intestinal toxemia, psychogenesis, endocrine anomaly and cerebral lesion is sufficiently fundamental and comprehensive to explain adequately or to point the way to rational and effective treatment. Thus idiopathic epilepsy has largely come to be considered but a manifestation of many diverse causes rather than a diathesis or dyscrasia as was formerly the case. The tendency toward considering all epilepsies as symptomatic is not without its dangers, among which is that of inhibiting investigation along other lines, for it is apparent to many that beside the organic defect some other factor must be present in order to bring about the convulsive explosion.

It has seemed to the writers that a phenomenon so constant in its character must have a fairly constant immediate etiological basis, however diversified the antecedent factors may have been. W. T. Shanahan, medical superintendent of the Craig Colony, in his last annual report (1) states "To those familiar with the epilepsies there can be but little doubt of the fact that a defective nervous system acted upon by a chemical substance of some unknown makeup and origin is the explanation of the exciting etiological factor. These defects are multiple in nature and so in like manner, the offending chemical substance may be of varying formulas in different cases. We find apparently the same defects in non-epileptics."

Within the last few years the tremendous value of the observations of Richet, Arthus and Theobold Smith upon the phenomena of anaphylaxis have come to be realized and as a result of numerous investigations by many observers baffling problems of etiology, diagnosis and treatment in hitherto obscure conditions have been wholly or partially cleared up; most notably in hay fever and urticaria, in a large proportion of cases of asthma and eczema, and in a number of other conditions such as angioneurotic edema, acute abdominal pains, and bladder irritability. In these conditions allergy and hypersensitiveness have been found to be a frequent and important factor. It is not surprising therefore that when so many heretofore obscure phenomena were so readily explained and when it was observed both in animal experimentation and in clinical observation that convulsions are very often a manifestation of a definite anaphylactic shock that epilepsy should be included among the possible conditions in which allergy is an important factor.

It is not uncommon for the anamnesis of epileptic patients to show that the onset of convulsions followed and was attributed to the ingestion of some particular food, such as eggs, pork, cabbage, bananas, which had before not been included in the diet or if so had before not agreed with the patient. Physicians have been prone to discount this evidence, conceding the possible influence of gastrointestinal irritation but ignoring specificity. Convulsions in infancy, sometimes persisting in later life, often date from the introduction of foods other than breastmilk into the dietry. Thus E. G. and D. G., sisters, aged eleven and eight, showed convulsions at the ages of eight months and ten months, when first changed from breastmilk to a modification of cow's milk. The convulsive attacks have persisted until recently. A. M., a girl aged seven, showed convulsions at the age of four months, when she was changed from breastmilk to a carbohydrate preparation called groats, and which persisted at intervals until the age of seven months when she was put upon modified milk. H. B., a boy aged eleven years, showed convulsions at the age of three months, when he was given a carbohydrate gruel prepared from cracker crumbs. The convulsions persisted until arrested by treatment three months ago.

Socalled fits in animals usually occur after the eating of unaccustomed foods, especially in cats whose idiosyncrasy to pork is well known. Spratling, writing in 1904 (2), states: "Finally, individual susceptibility to certain foods, harmless in most persons, but poisonous in others, should not be overlooked; such foods usually consist of shellfish, and certain fruits, including peaches and strawberries."

Later in the same work (page 134) he mentions the case of a boy who had a convulsion at the age of one year, (probably when put on cow's milk.—Author's note) with no recurrence until the age of eleven, when he was vaccinated, and his body became covered with a general scaly eruption with the immediate appearance of convulsions which became permanent in character. This the writers surmise was an instance of hypersensitiveness to bovine products, a condition which they believe to be not unique. Ward (3) reports convulsions in a girl sensitive to cow's milk, cheese, casein, beef and veal, whose attacks ceased when all bovine products were excluded from her diet. M. C., aged nine years, a patient of one of the writers, had ber first convulsion at two years after eating a banana, and while ordinarily her attacks are controlled by treatment, indulgence in this fruit, and in chocolate, tomatoes and potatoes will bring on a convulsion. She presents a definite skin reaction to tests with each of these foods.

Spratling mentions (*idem*) a young man, previously free from convulsions who was severely stung by bees about the face and whose convulsions ap-

*Read before the College of Physicians of Pittsburgh, January 25, 1923.

peared regularly every two weeks thereafter. J. M., a boy of sixteen, a patient of one of the writers some years ago, would invariably have a convulsion after the smoking of a cigarette, though free from them when not using tobacco. G. E. N., a normal child of three and one half years, who had in early childhood shown hypersensitiveness to egg by the appearance of urticaria, and from whose diet egg was then eliminated, received a portion of an egg through the carelessness of a servant and responded with the usual symptoms plus a severe prolonged convulsion and is now, seven years later, a feeble-minded mute. S. C., a boy aged six years, received several large doses of antitoxin for suspected diphtheria, which proved to be a simple angina, in whom there developed a convulsion and he continued to manifest major convulsions with frequent *petit mal* attacks. In H. S., a boy of ten years, there developed convulsions after vaccination. Instances might be multiplied both from the literature and from personal case histories in which there is apparently a direct relationship between the introduction of a foreign substance into the economy and the onset of convulsive attacks.

Novy and De Kruif (4) make some significant observations relative to anaphylaxis which, the writers believe, are pertinent to the present discussion. They say "It is important to realize from the medical viewpoint that inducing substances may develop within the normal animal through some unrecognized cause which may lie in a peculiarity of diet, or in exposure, or in obscure infections, etc. As a result, the blood of such an animal will be abnormally toxic because of the presence of anaphylatoxin or taraxin. This condition has actually been observed in normal untreated rabbits. A similar condition is without doubt of frequent occurrence in man and while the amount of poison thus produced may not be sufficient to cause an acute anaphylactic or teraxic shock, it may lead to a subacute or chronic form of intoxication. The sudden formation of much anaphylatoxin or taraxin may bring on the explosive effects seen in eclampsia, and perhaps in surgical shock, not to mention other attacks with rapid onset. The gradual production and presence of such poison may result in the obscure effects noted in connection with some of the socalled autointoxications, and it may lead to anemia, cachexia, etc. Lastly and not the least, it is also to be remembered that a considerable part of the toxic effects in infectious diseases is in all probability due to the formation of anaphylatoxin or taraxin. In other words, infection leads to taraxy. The great and far reaching importance attaching to this problem will be evident the moment it is realized that the circulating blood, through a variety of agents, may be changed from a beneficial and harmless to an injurious and poisonous state. The alien substance is merely the trigger which, so to speak, ignites or explodes the charge contained within the bloodvessels."

The preceding observations are sufficient, the writers believe, to indicate the basis upon which they postulate an intimate connection between the phenomena of anaphylaxis and allergy and the phenomena of idiopathic epilepsy. Proof requires further investigation in many fields. Why an anaphylactic shock should eventuate in convulsions instead of the more usual phenomena opens up another fertile field for speculation. Besredka (5) assumes that the shock in anaphylaxis is due to the direct toxic action of protein split products upon the cells of the central nervous system. "The experiments of different authors, however, have definitely shown that the central nervous system is not primarily, but only secondarily involved in the anaphylactic symptom complex." (*Idem*) Perhaps a predisposition to convulsions exists because of inherent organic inferiority (inherited or acquired) of the cerebral cortex. Perhaps certain protein split products possess a specificity for certain cells, in which case convulsive crises may occur rather than bronchial, gastric or other phenomena. The resulting nerve cell pathology or nerve cell irritability may be the foundation for subsequent convulsive crises either with or without an anaphylactic basis.

The case records of the writers contain notes of so many cases in which convulsive attacks, aphasia, hemiplegia, amentia and other indications of organic brain injury have followed the use of diphtheria antitoxin, vaccination and the ingestion of certain foods that they cannot but feel that the phenomena of anaphylaxis and allergy are factors of great etiological significance. Except by analysis of the anamnesis, and occasionally where sensitiveness to the offending substance has persisted, there is at present no sure way of isolating the exciting cause. Skin tests may show single or multiple sensitiveness or may show sensitiveness to none of the usual allergins. This because sensitiveness may have been only temporarily present in the subject, he may have become desensitized or because the existing anaphylactic tendency is toward some unusual substance not included in routine tests or which resides in some complex state of body chemistry. The labors of many workers in many fields will be necessary to solve the problems involved.

Nonspecific as well as anaphylactic reactions are elicited most frequently by colloidal substances, either injected therapeutically or originating in the tissues as a result of some inflammation (turpentine injection, burn, trauma, etc.). Of the various colloids we find the proteins and their derivatives most commonly used.

The native proteins consist of exceedingly complex molecules which in turn are built up of combinations of aminoacids. Chemically, the proteins are relatively stable and inert and are amphoteric (combining with both the hydrogen and hydroxylion). They can be hydrolyzed by acids, alkalies and enzymes yielding a series of degradation products commonly referred to as protein split products. These latter vary in character, amount and decomposition with the protein undergoing lysis and the method used in bringing disintegration.

The ultimate molecular units from which the proteins are constructed, are the aminoacids. In general, the lower split products of the proteins, including the aminoacids are relatively nontoxic and bring about little or no reaction on the part of the patient when injected. The compounds containing the various ring groupings of the carbon atom as

well as the diamino group, seem to be exceptions. The toxicity of histamine is well known, especially its ability to procure convulsions. More recently the presence of histamine and other toxic amins have been demonstrated in the bowel of cases of intestinal obstruction and the toxic symptoms of this condition have been attributed to these poisonous protein decomposition products. Histamine, like other amines, may arise through putrefactive changes in protein containing materials and is therefore among the more potent of the bases to which bacteria may give rise. Microorganisms capable of producing amines have been isolated.

A number of procedures, essentially nonspecific in character, have been tried in the treatment of epilepsy, beginning with the use of serum injections by Ceni (6) in 1903, brain extract by Lion (7) in 1911, cerebrospinal fluid by Gordon in 1914 and immune rabbit serum by Held (8). Turner treated twenty-three cases with colloidal platinum injections and noted a diminution in the number and intensity of the attacks.

Dollken (9) used a combined milk and luminal therapy, adding to the milk injections a small quantity of vaccine of nonvirulent organisms and gave injections twice weekly. Twelve cases were free from attacks for a period of eighteen months and sixty for one year. In thirteen cases there was no complete cure but a definite improvement was noted.

Edgeworth (10) in a series of twenty-three cases, injected a five per cent. solution of peptone at weekly intervals, giving five, ten, fifteen and twelve minims. Toxic symptoms were observed in four cases. In forty per cent. of the cases so treated, the attacks ceased.

Geyelin (11) has recently reported that fasting may at times be followed by the cure of epilepsy. Whether the therapeutic effect is dependent on the acidosis involved in this method, and thereby related to other nonspecific shock effects, has not been established.

In the writers' experience with this method convulsions have returned with their usual intensity soon after the patient returned to a normal diet and to full activity.

In the present state of our knowledge radical measures based upon the assumption mentioned above must be avoided, for the state of the epileptic is pitiable enough without incurring the danger of rendering it worse by injudicious therapeutic activity. If the offending substance or substances are still active they may be apprehended by the method suggested by Duke (12) in determining hypersensitiveness in other classes of cases. His sources of information are: 1, family history; 2, personal history; 3, examination; 4, observation by the patient, and 5, specific tests (cutaneous, ophthalmic, nasal, subcutaneous, clinical, etc.).

If an offending protein or other substance is found it should be removed from the diet or environment of the individual. In addition the immunity threshold should be raised by every means within our power. This may be done by following the measures, hygienic, medical and educational, detailed by one of the writers in a previous contribution. (13).

The authors' references will appear in his reprints.

The Use of Luminal in the Treatment of the Excited Phases of Mental Illness

L. D. HUBBARD, M.D.,
Washington, D. C.

In view of the excellent temporary results reported from the use of luminal in epilepsy, an attempt was made to determine whether this drug would quiet patients in excited periods of mental illness, and, if so, what classes of such patients were most benefited. A group of thirteen colored women patients were chosen to receive treatment. Of these, seven suffered from periodical excitements and six were in a state of continuous excitement. As to diagnosis, eight were dementia precox cases, two manic depressive, two general paresis and one a mixed psychosis showing preponderantly precox features, so that it will, for convenience, be put in that group. In age, they ranged from thirty-five to seventy-four, five being between thirty-five and forty-five, five between forty-five and fifty-five, one between fifty-five and sixty-five, two between sixty-five and seventy-five.

In the cases of periodical excitement, charts were kept for some time prior to the administration of the drug, so that an accurate idea could be gained of the usual course and duration of the disturbance. This having been accomplished, the luminal was given at the first indication of upset. All the periodical excitements under consideration went into their disturbed attacks rather suddenly,—either over night or in the course of one to three days. The nurse in charge of these patients had watched them carefully for a long period, in some cases for as much as two years, and was well acquainted with the behavior changes which heralded a storm. The drug was given in moderate doses at first, three grains a day, so that any untoward effects could be observed at once. If necessary the amount was raised to four and a half grains, or one tablet three times a day. This amount was never exceeded.

The dose of the drug was regulated much the same at first in the continuous excitements. Its withdrawal was usually gradual, but in one or two instances the subject was started with four and a half grains and after a time it was abruptly withdrawn. No difference was noted in the effect.

Two of the patients showed a definite marked increase in the severity of their symptoms beginning about twenty-four hours after the first dose of luminal and lasting until it was discontinued. One of these was a woman in her thirties suffering from

general paresis. She was a strong muscular light colored woman who, for the entire six months of her hospital life, had scolded, picked fights with other patients and destroyed furniture and clothing. Although never quiet previous to the luminal therapy, she became noisier, more irritable and more savage in her attacks on other patients. The drug was given intermittently, in varying doses, for a period of three weeks, but at no time could any beneficial results be observed. The other patient whose excitement showed an increase was a gaunt dark woman of fifty-two, who had been in the hospital about two years and a half. She was a typical case of dementia precox, full of delusions, talking constantly, destructive, untidy. She had been in the hospital two years about ten years before the present admission. Luminal therapy was begun as described above but her condition became so much worse that it had to be withdrawn after a few days.

Five patients showed no change whatever. These were three precox cases, one paretic in a continuous excitement, and one manic depressive. No matter how abruptly the doses were increased or withdrawn, the disturbed condition showed no change of character or intensity. One, a forty year old hebephrenic precox, had been excited for the three and a half years since her admission. Another hebephrenic, aged forty-five, had been ill six years and continuously excited three years. The third precox, in the hospital six years, had been excited a year and a half. The paretic had been in a gradually increasing excitement several months. The manic depressive was a woman of sixty-seven, three years in hospital, and suffering with typical affective swings separated by an approximately normal period. Following a depression, she was in good condition four months and then began to show signs of excitement. Luminal was given in large doses but the excitement showed its usual course and the treatment was discontinued. After four months the patient quieted down again, that being the usual duration of the excitement.

The periodically excited patients showed a somewhat better reaction. There were six of these who showed some change after the administration of luminal—one manic depressive and five precoxes. Three showed change in the character of the attack and three in duration. The manic depressive patient was admitted for the fourth time six years ago and is now forty-four years old. Her excitements were frequent and severe. In three successive attacks luminal was given from the first day. In no instance did the excitement subside nor was the duration of the attack shortened. There was, however, a definite change in behavior. From a pugnacious, irritable, resistive patient, she became goodnatured, jolly and mischievous. She was much easier to care for and did not do half as much harm to herself or her environment as in previous attacks. Another patient, a precox aged sixty-two, who had been in the hospital sixteen years, was also subdued by the treatment without shortening the attack. She became drowsy, eyes were bloodshot, gait unsteady. If she could have been treated in bed, it is probable that the results would have been excellent, but she retained her negativism in spite of her drowsiness and the treatment had to be abandoned. A fifty year old precox, subject to violent and long continued excitements during the ten years of her stay in the hospital, was benefited to the extent of becoming goodnatured, duration of the excitement remaining as usual.

The three patients whose excited periods were shortened were all cases of dementia precox. One was a woman of seventy or more who had spent most of her life in hospitals for the insane. Her excitements usually lasted about a month with a somewhat shorter quiet interval. Following thirty-three days of quiet, an excitement began and she was at once given luminal, two tablets a day. On the eighth day she was quiet and the medicine was gradually withdrawn. Nineteen days later she was again excited. Three grains of luminal were given and she was quiet next morning. The next day she was excited and the dose was increased to four and a half grains. After one day of quiet, she was excited two days and then remained quiet six weeks, the luminal being discontinued on the fifth day. The following month she was partially excited about two thirds of the time, showing an increase or decrease of excitement in response to decrease or increase in the dose of luminal. She finally became quiet and remained so for six weeks.

The second precox, a resident of the hospital for twenty-five years and now about fifty years of age, was subject to excitements of varying lengths. Following three months of quiet, an excitement came on and luminal was administered. For five weeks she was quieted by luminal for a few days and became excited again as soon as it was withdrawn. A quiet month followed and then an excitement developed which yielded twice to luminal and then showed no further effect. The drug was withdrawn on the tenth day of undiminished excitement and the patient was not quiet again for four months.

The last patient was a woman of thirty-eight who had been in the hospital only six months. Periodical excitements, increasingly severe, had been present for three years prior to admission. She also had syphilis, an arrested pulmonary tuberculosis and an enlarged thyroid, which, however, gave no reaction to tests for endocrine disturbance. Her excited periods were characterized by rapid striding up and down the ward, constant loud scolding and refusal of food. After four or five days of this she would be practically exhausted. Hydrotherapy had no effect. Luminal stopped the excitement within three days the first three months it was used. The next month an excitement lasted twelve days but differed from previous attacks in that she was quiet a large part of each day. This change persisted in subsequent excitements and was of advantage to the patient because she no longer became exhausted and emaciated.

SUMMARY

Thirteen colored female patients suffering from excited phases of mental illness were treated with luminal. Doses ranged from one and a half to four and a half grains daily. Seven periodical excitements and six continuous excitements were thus treated. Ages of patients ranged from thirty-five to seventy-five. Nine were cases of dementia precox, two of general paresis and two of manic depressive psychosis.

Two cases, one general paretic and one long standing case of precox, showed definite increase in the severity of the symptoms.

Five cases showed no change whatever. These were three precox cases, one general paretic and one manic depressive.

Of the remaining six, three showed a change in the character of the excitement, two showed a shortening of the excited period and one showed both change and shortening. The change in all four cases was for the better. Three patients usually destructive, pugnacious and unmanageable, became silly, mischievous and good natured. One changed from a state of activity lasting day and night and resulting in exhaustion, to an intermittent activity which left her quiet a part of each day. In the three cases where the excited period was shortened, the symptoms came on as soon as the luminal was withdrawn, and ran its usual course.

St. Elizabeth's Hospital.

Mechanical Aids in the Localization of Brain Tumors

FRANCIS G. GRANT, M.D.,
Philadelphia

In a certain number of cases in which brain tumor is suspected, approximately thirty to thirty-five per cent., it is impossible to arrive at a satisfactory localization of the lesion by means of the ordinary neurological examination. Complete eye and ear studies are now included as a routine in every obscure case. A neurologist must know sufficient ophthalmology to recognize the significance of visual field defects, papilledema, or optic atrophy and have enough knowledge of otology to appreciate the localizing value of the Bárány reactions.

Even with the information to be derived from careful study of the function of the second and eighth nerves, our knowledge of the position of the neoplasm is often far from exact. Since brain tumor is a condition in which surgical removal affords the greatest hope for relief, the localization of the growth must be certain if an attempt at extirpation is to be successful. Owing to the physical and mechanical difficulties under which the surgeon must work, the area of the brain that can be exposed and explored is limited. Moreover, it is essential for him to know not only the area of the brain involved but also whether the tumor lies on the cortex or is buried beneath it. Therefore, when the usual routine examinations fail we fall back on mechanical aids to furnish us with the information we must have if successful surgery is to be anticipated.

These aids are, first, x rays, by means of which bone changes in the skull and calcifications in tumor tissue may be determined. Hence the position of the tumor will be revealed and defects in position, size and shape of the ventricles demonstrated after the intraventricular injection of air. Secondly, estimation of the size and shape of the ventricles, by tapping both posterior horns and injecting a dye solution, may give important evidence of the position of the lesion.

Finally, the determination of the degree of tissue resistance by the use of the bipolar electrode needle may reveal the pathological process lying beneath an apparently normal cortex. If after a localization made by the ordinary routine methods the surgeon exposes the suspected area and finds a cortex normal to inspection and palpation, he hesitates to make a transcortical incision. If he cuts into the brain and finds no lesion the damage he does may be irreparable. It requires undoubted evidence of the presence of a tumor beneath the cortex to justify deeper exploration.

If an x ray plate of the head be taken and the shadow due to calcification within a tumor revealed, the localization is positive. Unfortunately this is a relatively rare occurrence. Only about one to two per cent. of tumors show calcification. Pathologically these tumors are usually endothelioma, although cystic suprasellar tumors originating in Rathke's pouch may show calcification in the cyst wall. The meningiomas may show marked thickening of the cranial bones over the tumor. This increase in the depth of the bone is probably due to an infiltration by endotheliomatous cells. Localized thickening of the cranial vault on an x ray plate is of much importance as presumptive evidence that a tumor lies beneath. Erosion of the floor of the sella or of the anterior and posterior clinoid processes occurs with intrasellar and suprasellar growths.

This is mentioned merely to emphasize the fact that erosion of the clinoids is not always due to neoplasm in the neighborhood of the pituitary. Posterior fossa lesions causing marked internal hydrocephalus and dilatation of the third ventricle may produce as marked a destruction of the bony processes about the sella as suprasellar tumors. As the third ventricle dilates downward with the increasing hydrocephalus, its pressure often causes complete disappearance of the clinoids. In the past three years we have seen six cases of cerebellar lesions simulating, from the x ray viewpoint, suprasellar tumors.

In ventriculography the actual tapping of the ventricles, the removal of the fluid and the injection of air is the simplest part of the procedure. It is the correct interpretation of the ventricular shadows on the x ray plate that determines the success or failure of localizing the growth. Since reporting results with ventriculography a year ago, my series includes eleven more cases. That an accurate localization of the tumor was made was confirmed in six cases. In four cases while probably accurate, and the neurological picture seems to confirm our conclusion, positive evidence of the exactness of our findings was not obtainable. In one case we were

misled by our interpretation of the x ray plates. One patient died suddenly six days after the insufflation and removal of the air. He had been symptom free while prone but he sat up and left his bed. He complained of dizziness and died suddenly five hours later of respiratory collapse. Autopsy revealed a correctly localized lesion in the posterior fossa. No foraminal cone about the cerebellum, hemorrhage into the ventricles, or other cause for his death was apparent.

Our attitude towards ventriculography is as follows: We consider it rather as a last resort in localization. If the neurological signs are at all convincing we operate in the area they suggest. If this exploration is negative or if only general signs of tumor without localizing evidence are present we feel that it is justifiable to assume the risk accompanying ventriculography. All operators, save Dandy, have experienced a five to ten per cent. mortality from the air injection. This is too high unless we are certain that a tumor is present and that we cannot locate it by less hazardous means. The mortality from unoperated and unchecked brain tumor is high enough to justify any risk to determine its position. But the unfortunate fact remains that most tumors localizable by ventriculography have reached such a size or are so deep seated that surgical removal is impossible.

Since the mortality rate in air injection is unquestionably high, particularly in cases in which a tendency towards stupor exists, Dandy has suggested ventricular estimation as an alternative measure of localizing value under these conditions. In ventriculography it is necessary to tap the posterior horn of both ventricles. The trephine opening is always made with precisely the same relationship to the occipital protuberance. Normally the ventricle is encountered at the same depth from the surface and the same distance from the midline. On the average, an undilated ventricle contains twenty-five to forty c.c. of cerebrospinal fluid, and should be encountered at a distance of about five centimetres from the surface of the brain.

If following trephine and tap one ventricle seems much larger than its fellow or if one ventricle is not encountered at the normal depth or in the usual position but seems to have been dislocated, this is good presumptive evidence that the cause for its abnormal position is the presence of tumor. With one ventricle smaller than the other the tumor is on the side of the smaller ventricle. If bilateral dilatation of both lateral ventricles exist and if a dye as indigocarmine is injected into one lateral ventricle and recovered on tapping the other, showing that the foramina of Monro is patulous, an internal hydrocephalus is present. The lesion then must lie below the foramen of Monro in the midline or in the posterior fossa. If the dye injected into the lateral ventricle is recovered by cisternal or lumbar puncture the cause for the hydrocephalus lies outside of the basilar cistern and is presumably a meningitis with adhesions.

We have made use of this means of determining the approximate position of a tumor four times. The information derived always fitted into the clinical picture. On one occasion a marked difference in the size of the lateral ventricles led us to the correct opinion that the lesion was supratentorial rather than infratentorial. In three cases of the four, our findings were confirmed. None of these patients showed any ill effects from ventricular tap. This is a simple matter and unless the tumor be in the occipital pole in the line of insertion of the cannula no harmful effects should be expected. If the tumor be in the occipital pole and extend into the ventricle, penetration of the tumor by the cannula might cause hemorrhage into the ventricle or into the tumor. Should this occur, a serious reaction might follow. But compared to ventriculography, ventricular estimation is safe.

Four years ago, two German observers, Meyer and Schluter (1), reported their results from the use of a method of determining tissue resistance. They developed an apparatus whereby the resistance of living tissue to the passage of an electric current could be discovered with sufficient accuracy for clinical use. Briefly the method used is as follows:

The wellknown principle of Wheatstone's bridge was adapted so that a known resistance was introduced into one arm of the circuit. A fine needle containing two platinum wires carefully insulated one from the other, one running to the tip of the needle and the other to a point on the shaft about a centimetre below the tip, so that the current must pass from one contact to the other to complete the circuit, was joined to another arm of the bridge. An audiooscillator, a tuning fork vibrating to an electric current and a calibrated sliding contact for reading accurately the relationship between the known and the unknown resistance were also placed in the circuit. As the needle containing the break in the circuit penetrates into the brain, the current passes from the wire in the tip to return through the wire on the shaft, and the tissue in which the needle is placed sets up a resistance to the passage of the current. This unknown resistance in one arm of the bridge is compared to the known resistance in the other arm of the bridge by estimating the intensity of the sound produced by the tuning fork or audiooscillator as heard in an ordinary radio earphone. The sliding contact is moved up and down its wire until the high pitched hum from the tuning fork disappears. Then the resistance is read off on the calibrations on the slide. This apparatus is compact and can be used in the operating room. The needle to be introduced into the brain is smaller than the cannula used to puncture the ventricles. We have used this apparatus in nineteen cases and have found in every instance that tumor tissue produced a markedly different resistance from normal brain tissue. Gliomatous tumors especially show a marked drop in their resistance to the passage of the current when compared to the normal brain. This resistance change can be demonstrated in formalized brain tissue as well as in the living brain. We have at present no explanation for this difference in the resistance of normal and pathological tissues to the passage of an electric current.

The importance of this method of determining the presence of a subcortical gliomatous lesion is great. Endotheliomata, of course, may by their difference in structure and their greater density give a

greater sense of resistance to an exploring cannula. Not so with glioma. There is no difference to the tactile sense on passing from normal to gliomatous tissue. It is in these cases that the change in electrical resistance will be of the greatest value. Given an apparently normal cortex on laying back a bone flap, if exploration with the electric needle shows that there is a marked difference between the resistance on the surface and in the depths of the brain, it is certain that a lesion lies below. A transcortical incision is then justifiable. It is our hope that eventually we may bring this method of determining the presence of a tumor to such a degree of accuracy that by exploring through a small trephine opening in the skull, an area in which a tumor is suspected, we may be able to establish or exclude the presence of a lesion. The exploring needle is so small that but little damage will be done to that part of the brain through which it is passed.

In conclusion it is our opinion that in the majority of cases, nothing can supersede careful neurological examinations in the localization of brain tumors. But there are cases in which all the signs of general intracranial pressure are present, while the symptoms of localizing significance are extremely vague. It is under these conditions that we suggest the use of these mechanical aids in diagnosis and localization of the lesion. They require special apparatus and experience in its use, but an accurate knowledge of the position of the tumor may thus be gained which can be obtained by no other methods.

Amaurotic Family Idiocy*

J. EPSTEIN, M.D.,
New York.

Amaurotic family idiocy is a disease of early infancy. It has an unknown etiology, a definite pathology, a uniform clinical course, and a fatal prognosis. It is chiefly characterized by an early decay of body and mind, blindness and death. Various names were given to this disease of which amaurotic family idiocy, Tay-Sachs disease, infantile cerebral degeneration with symmetrical changes in the macula lutea, and primary amaurotic mental deficiency are best known. But infantile amaurotic idiocy would perhaps be more descriptive of this disease, because it occurs only in infants, amaurosis is always present and idiocy is a constant symptom. It is an uncommon malady and for some obscure reason it affects almost exclusively Jewish children of Russian or Polish parentage. In many cases more than one child in a famiily is affected.

The etiology of this remarkable disease is unknown. The age of the parents, the number of children in the family, and their order of birth have no direct influence. Marked neurotic taint in the family, blood relationship between the parents, traumatic injury to the pregnant mother and toxemia in the child have all been assigned as causes.

The pathology is fairly definite. It is a disease of the central nervous system consisting of a degeneration and disintegration of the nerve cells and ganglia of the brain and spinal cord, leading to neuromuscular weakness, mental deterioration, blindness and death. There is probably a primary cessation of development of the central nervous system and a secondary gradual destruction of the nerve cells.

The symptomatology is that of physical and mental retrogression. An apparently normal healthy baby at birth, begins at about the age of six months to show evidence of general backwardness. The normal developmental progress of infancy ceases and a gradual decadence takes place. The baby loses the power to hold up its head, cannot sit up or carry out properly the usual motor functions of early life. It becomes oblivious to its surroundings and the face assumes a dull, vacant, aimless, idiotic expression. As a result of optic atrophy and degeneration of the retinal ganglia, the power of vision is gradually lost and there is formed a peculiar cherry red spot in the region of the macula lutea and fovea centralis of each eye. Hearing, as a rule, becomes hyperacute. In the beginning of the illness there is a general muscular weakness with slight flaccidity or spasticity of the extremities and a diminution or increase in the reflexes. Nutrition is usually good. In the course of the disease the child loses entirely the power of vision, there is marked spasticity with increase in the reflexes and general or local spasms. It wastes to a skeleton and lies in a helpless condition till death, coming always in the wake of this hopeless disease, finally ends the struggle.

The diagnosis is comparatively easy. The history is always suggestive. A healthy, usually breastfed infant and thriving both physically and mentally begins at about the age of a half year to go downward in body and mind without any definite cause. There is a certain peculiar facial characteristic which is only expressive of this disease. A general physical examination will show changes in the neuromuscular system. There may be paresis of the extremities with slight increase in the reflexes or a general spasticity with exaggerated reflexes. There is usually a strong hyperirritability of the nervous system, so that when the child is suddenly touched or moved it starts as if in fright or may have a general convulsion. Nystagmus and strabismus are not infrequent and hyperacusis is almost constant. An ophthalmoscopic examination of the eyes is essential to a proper diagnosis. In every case of infantile amaurotic idiocy there is seen a circular cherry red spot surrounded by a grayish white halo in the region of the fovea centralis and macula lutea, as shown in Fig. 1. This retinal red spot on a

*From the Pediatric Clinic of Beth Israel Hospital.

whitish background is so pathognomonic of this disease that its presence makes the diagnosis positive while its absence is strong evidence against such a diagnosis. The course of this disease is in all cases almost uniform and its termination is always fatal.

This infantile amaurotic disease should be distinguished from the juvenile type of amaurotic

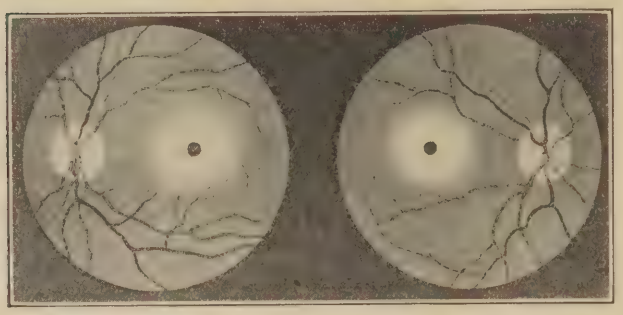

Fig. 1.—The eye grounds in amaurotic family idiocy. From an original drawing by Warren Tay in *Diseases of the Eye*, by Norris and Oliver. Note the circular dark spot in centre of whitish field.

idiocy. The juvenile type occurs at a later age, is not restricted to the Jewish race, and has not the retinal red spot. The onset is more insidious and the disease is more chronic. The infantile type is illustrated in the following cases.

Case I.—V. S. A female infant, fifteen months old. The parents are young, healthy Russian Hebrews. No history of syphilis or other infection in the parents, no parental blood relationship, no taint of neuroses or psychoses in either family. The patient was the first and only child. Pregnancy, birth and lactation were normal. At about five months of age the mother noticed that the child was not developing properly, she also thought that the baby was never just right. On examination there was seen a well developed, well fed, stupid looking baby with the facial characteristics of an amaurotic idiot. The anterior fontanelle was open, the posterior closed. There was a general superficial glandular enlargement. There were two lower incisor teeth. Examination of the heart, lungs, and abdomen was negative. Vision was impaired and there was slight strabismus. The baby was unable to sit unsupported. Wassermann and Pirquet tests were negative. An ophthalmoscopic examination revealed the cherry red spot. The child gradually grew worse and became totally blind. Spasticity became marked and the reflexes much increased. There was great hyperacuity and hyperirritability with frequent attacks of local or general spasms. No Kernig or Babinski sign but the Chvostek sign was present. The baby became greatly emaciated and lay in a helpless condition until a bronchopneumonia made an end to her suffering at the age of twenty-three months.

Case II.—H. G. A male infant, ten months old. The parents are healthy Jewish people, no history of syphilis, alcoholism, or any other chronic ailment, no parental consanguinity. This baby was the third child in the family. The first and second were alive and well. Pregnancy, birth and lactation were normal. The health and development during the early months of life were noneventful. At the age of about half a year it was noticed that the baby did not hold up its head properly and was not bright enough for his age. Examination showed a well developed foolish looking baby. The weight and measurements were normal for the age. Anterior fontanelle was open, had six teeth. Examination of the chest and abdomen was negative. There was spasticity of the extremities with exaggerated reflexes. Vision was almost entirely gone. The typical cherry red spot was present in each eye. Pirquet and Wassermann tests were negative. The child was not brought for further examination. He has no doubt succumbed to this relentless disease.

Case III.—R. S. A female intant, the seventh child of healthy Russian Hebrew parents. First cousins. No history of any chronic illness or psychoses. The child was born at full term, the labor and the breast feeding were normal. Two months before this child was born, her sister, who was the sixth child in the family, died of amaurotic idiocy at the age of twenty-one months. The other children are alive and well. When the baby was only a week or two old the mother noticed that she was very hypersensitive to sound. Between the fourth and seventh month of age she had frequent twitching of the upper eyelids. At the age of eight months the child was unable to raise its head and did not make any effort to sit up. She was dull, listless, and paid no attention to familiar people or objects. At ten months of age, a general physical examination was negative. The anterior fontanelle was open, the posterior closed, cranial sutures closed. There was no nystagmus or strabismus and the child could see fairly well. But an ophthalmoscopic examination already revealed the cherry red spot in each eye. There was no apparent change in the neuromuscular system. The Wassermann and Pirquet tests were negative. At the age of eighteen months there was a marked decline in motor function and a general spasticity with increased reflexes. The face was idiotic, vision almost gone, and hyperacusis was marked. Between the eighteenth and the twenty-third month she grew rapidly worse.

She lost a great deal in weight and became wasted to a skeleton. The anterior fontanelle was now larger than at ten months of age, the posterior fontanelle opened and the cranial sutures separated, due evidently to an accumulation of fluid in the cranial cavity. There was total blindness and an idiotic expression. The mouth was kept almost locked, general spasticity and episthotonus were marked and the reflexes much exaggerated. No Kernig or Babinski sign, no ankle clonus, but the Chvostek sign was present. There were frequent attacks of tonic and clonic convulsions and occasionally facial spasms. At twenty-five months of age the child was in a state of extreme atrophy. She lay in a helpless condition with the arms and legs extended, the hands flexed and contracted and the feet markedly extended. During the twenty-fifth month of age the infant died.

Case IV.—S. L. A male infant, eleven months old. He was the first of young healthy Jewish parents. There was nothing of importance in the parental history, no consanguinity. Pregnancy, birth, and lactation were normal. He was considered a normal child till eight months of age, when it was noticed that he was not doing well. He was dull

and indifferent, could not hold up his head or sit up. Examination at eleven months showed a well developed baby with a careless facial expression, a blind, aimless look, and an occasional silly smile. The anterior fontanelle was open, he had four teeth, examination of the heart, lungs and abdomen was negative, there was slight spasticity of the extremities with an increase in the reflexes. The child was almost blind and had the typical cherry red spot. The measurements were normal and the Wassermann test was negative.

Fig. 2.—Case II. H. G., an amaurotic idiot, ten months old.

Case V.—S. G. Was a male baby seventeen months old. The father and mother were young, healthy Jews. No history of syphilis, tuberculosis, or any other chronic infection or intoxication, no parental consanguinity. The patient was the second child; the first died of pneumonia at eight months of age. Pregnancy, birth, lactation, and the development up to the age of seven and a half months were normal. At this age the child was sick for three days with high fever and was in a semicomatose condition. No diagnosis was made by the attending physician. Immediately following this illness, the baby began to lose strength, could not sit up or hold up the head unsupported as it used to do before the illness. The entire disposition of the child was changed; he was dull, indifferent, paid little attention to his surroundings, and did not grasp objects within reach. At eleven months of age, the infant had an attack of convulsions. At seventeen months of age the child appeared well developed but was dull and listless. There was hardly any vision left. The typical circular cherry red spot in the macula lutea was present. The anterior fontanelle was open. He had four teeth. The chest and abdomen were negative. There was a general spasticity and increase in the reflexes. A fine tremor in the lower extremities was elicited during reflex excitation, no Kernig or Babinski sign, no nystagmus or strabismus, marked hyperacuity and irritability. The weight and measurements were normal for the age. The child died at twenty-two months. A year later the mother gave birth to a normal child who is two years old now and is well in every way.

Case VI.—Gertrude L. Twelve months old, second child. Pregnancy, birth and lactation were normal. The father was somewhat mentally deficient and one of his brothers was in an institution for the feebleminded. Still he was able to support and take care of his family. The mother and the older child were entirely well. No consanguinity. From early infancy the mother noticed that the baby was not as bright and active as other infants of the same age but was assured that it would outgrow its troubles. At eight months of age the mother realized that there was something wrong with the child. It never smiled, had a dejected, sad expression, and looked aimlessly around. Could not sit up or even hold up her head. At the age of one year the baby came under my care. It looked like the other amaurotic idiots; dull, stupid and indifferent. The anterior fontanelle was open, posterior closed, had five teeth, heart, lungs and abdomen were negative. There was a slight, general spasticity and an exaggeration of the reflexes with a marked Chvostek sign. The weight and measurements were normal. The typical cherry red spot was present on the fundi of both eyes. An x ray of the skull, urine examination, a Wassermann and Pirquet tests, a general blood count and an examination of the blood chemistry yielded nothing of importance that could be gleaned from as to the etiology of this elusive and destructive disease. A lumbar puncture was not permitted.

From an observation of these six cases and a few others that have come under my care, some interesting points have presented themselves. All these infantile amaurotic idiots came from parents that were apparently healthy and were young or at most of middle age. They all happened to come from about the same social and economic class. People that knew no privation, led a clean life, with clean habits. Pregnancy, birth, and lactation were normal in all cases. They all had the same peculiar characteristic amaurotic idiotic facies. The voice in all of them had a certain vibrating, snoring nasal quality, due probably to paresis of the soft palate. In all of them the disease passed through the same cycle of events with almost monotonous uniformity, and eventually all met the same fate.

The etiology of this disease and the reason for its predilection for Jewish children is as obscure now as it was when Warren Tay first described it in 1881. The disease is either congenital or acquired. In favor of its being congenital is the very early onset, the identical course of events, and the same termination in all cases. Such exactness and uniformity in the time of onset, the period of illness, and the pathological and clinical manifestations must evidently be caused in all of them by one and the same biological dysfunction. But whence does this mysterious illness come? The parents of all of them seemed to be healthy and apparently came from a healthy ancestry. Parental consanguinity was present only in Case III, and parental mental deficiency in Case VI. Only in Case III were there two children with amaurotic idiocy in the family.

Fig. 3.—Case VI. G. L., an amaurotic idiot, twelve months old.

This group of cases does not suggest a familial tendency to amaurotic idiocy. Still, the Mendelian

principle may perhaps supply the missing etiology.

Assuming that the disease is acquired, then the infant must be infected at birth or immediately after, and there is an incubation period of six or seven months at which time the disease manifests itself.

It is doubtful whether, as is commonly supposed, the infant is well up to about a half year of age and then almost suddenly begins to degenerate in body and mind without evident cause. In many cases it was noticed from early infancy that the children were not exactly normal in every way. There was at all times some evidence of physical and mental ailments. Case V suggests the possibility that in every case some acute illness may be the cause of the breakdown of the nervous system which was at no time equal to the task imposed upon it by the wear and tear of life. But the nature of this supposed nerve infection or intoxication is unknown. It may not be impossible that the much wanted etiology will ultimately be found in some abnormal action or reaction in the endocrine group which has a profound influence over the general metabolism and the life history of the nerve cells. Clinical and experimental cases of hypoparathyroidism and parathyreopriva strongly suggest an analogy between the course and manifestations of amaurotic family idiocy and parathyroid disorders.

There is no known treatment of any value in this disease. Proper feeding and the best hygienic care should be given. Bromides and warm baths are soothing to the irritable nervous system.

SUMMARY

Amaurotic family idiocy is a disease of many mysteries. There is no definite evidence of an hereditary taint, a congenital abnormality, or a latent infection that would throw any light on this destructive disease. That it is found exclusively among Jewish children is a biological enigma. The onset of the disease and the subsequent events in the life and death of the child indicate a degenerative pathogenesis of the central nervous system specially of the nerve cells and ganglia. While it manifests itself at the age of about six months, the exact time the illness begins is quite unknown. The cherry red spot in the macular region of each eye is characteristic.

The symptomatology is that of physical and mental recession. In an apparently healthy child at birth and for some months thereafter, there is a gradual and constant disintegration of body and mind. The diagnosis, in most cases, is comparatively easy. The age of onset, the peculiar facial expression of idiocy and blindness, the hyperirritability and the spasticity, and the cherry red spots make the diagnosis. The disease is chronic and relentless in its course, leading from health through a long degenerative illness to its final relief in death.

Blocking Off Remote Pain at the Nasal Ganglia*

HIRAM BYRD, M.D.,
Bradentown, Florida

The maladies which we loosely designate as neuritis (including sciatica), arthritis, and rheumatism have several traits in common, an outstanding one of which is that they all have a retinue of attendants, such as headache, nausea, sneezing, pain at other points, and so on. In a series of fifty cases I have found an average of three and five tenths symptoms to the case.

In forty-seven of these fifty cases not only the leading symptom but the entire retinue of attending symptoms could be blocked off by cocainizing the one or the other nasal ganglion.

Among these forty-seven are five cases of sciatica which are chosen for a more detailed report because they are generally better defined than other forms of neuritis, and because the number is not so great as to make the report too voluminous.

The three cases which I have been unable to block off will also receive appropriate consideration.

PAINS (NEURITIS, ARTHRITIS, AND RHEUMATISM), AND THEIR ACCOMPANYING SYMPTOMS THAT HAVE BEEN SUCCESSFULLY BLOCKED OFF AT THE NASAL GANGLIA.

Headache:	
Frontal	14
Temporal	5
Postauricular	1
Occipital	10
Vertex: Headache manifesting itself chiefly in the vertex is usually of sphenoid origin, and as will be seen later, cannot be blocked off.	
Eyes, pain in	9
Cheeks, pain and tenderness	8
Ears	1
Eustachian tubes (probably—description vague)	1
Throat:	
Soreness	3
Sense of tightness	2
Rasping	2
Upper teeth	1
Roof of mouth	1
Side of face	1
Neck:	
Down the side	5
Back of	5
Shoulder and arm:	
Shoulder joint	5
Muscles in front of	3
Arm, down its entire length	9
Spot at insertion of deltoid	1
Along nerve, forearm only	1
Elbow	2
Wrist	2
Metacarpus	1
Fingers	2
Trunk:	
Precordial pain and soreness to pressure	4
Pain in lung (?)	1
Pain and soreness between scapular and spine	2
Pain and soreness at lower border ribs	1
Pain and soreness at sacroiliac joints	5
Pain in lumbar region	4
Nausea	5
Weakness	5
Coughing	6
Dyspnea	3
Sneezing	2
Socalled nervousness	5
Dizziness	2
Globus hystericus	2
Uterine pains	1
Lower extremities:	
Pain on flexure of knee	5
Sciatica	5
Pain in thighs and legs (aside from sciatica)	3
Knees	6
Ankles	3
Metatarsus	2
Toes	2

*Epitome of address delivered before the Hillsboro County Medical Society, Tampa, Florida, July 17, 1924.

The following cases, bear in mind, constitute a complete serial of sciatica.

Case I.—E. R., aged twenty-five. Had had some nervous disturbance for several years, including such symptoms as nervousness, nausea, headache, weakness, exhaustion, pains and aches here and there, and even sore spots. One sore spot in particular, sometimes better, sometimes worse, but ever present, was located at the lower border of the ribs on the left side. This she dated to the cranking of a Ford some four years ago. Her general distress was such that she had gone West for a year or two, although the circumstances of the family were such that they could ill afford it.

When first seen she was nervous and undernourished, and suffering from recurrent headache, chiefly left temporal, and recurrent nausea, and from this sore spot. At this juncture the left nasal ganglion was cocainized with eight per cent. cocaine, which relieved the headache, and the sore spot. The latter has never returned.

Later she showed up with pain and soreness in the left sciatic nerve, reaching all the way down to the feet, and of a severity that made walking extremely difficult. It had come on rather suddenly and had persisted some three hours without cessation. When the left nasal ganglion was cocainized, it promptly disappeared, and has never since returned, now some two months.

I would not undertake to say that this was a case of sciatica and would not include it in this report except to make the series complete, although the only factor lacking to make a diagnosis of sciatica was the element of time, for had it continued no other diagnosis would have been possible.

Case II.—E. T., aged twenty-one. For the last six years she had had several attacks of sciatica that had kept her in bed four to six weeks each time. When first seen she was in the throes of an attack involving the right limb, and from which she had then been in bed two weeks. When seen she had a pillow propped under her right hip in an endeavor to find an easy pose. The right nasal ganglion was first blocked with eight per cent. cocaine but with entirely negative results. The left was then likewise blocked, but with a prompt reaction, the pain entirely abating, and leaving behind only a residue of soreness in the sciatic nerve. This is an important point and will be referred to again.

All treatment was now withdrawn and the patient remained up and about even driving as if she had never been afflicted. At the end of forty-eight hours the pain returned. This time she was brought to my office and the pain again blocked off from the left nasal ganglion, the right one being unmolested. Again there was a residue of soreness left.

Nasal examination with a Holmes lamp placed the left ethmoid region under suspicion. This was put under treatment with one per cent. silver nitrate applied every other day. This time the symptoms did not return for a week, and when they did, in modified form. Again they were blocked off and treatment continued for four weeks when she was dismissed as well.

This case reveals two points that are worthy of note. In the first place, though the trouble was with the right sciatic nerve, it could be blocked off only from the opposite side. Experience in nerve blocking indicates that *when the symptom is above the neck it can be blocked off from the same side only, but below the neck, from the same, or from the opposite side—never from either indiscriminately.*

The other point is that after the trouble was blocked off as completely as possible, and when no kind of motion would provoke pain, there was still a residue of soreness in the affected nerve. In a recent case of arthritis, or neuritis, all symptoms can be so completely blocked off that there is no trace left. But after a case has persisted for a time, there supervenes a soreness that is entirely refractory to all attempts at blocking.

As I interpret this, in a recent case of arthritis, neuritis, or rheumatism, that can be blocked off entirely, there is chiefly an impulse[1] to deal with—a something that is being sent along the course of the nerves from some distant point to the locus of distress.

All one has to do to stop the pain is to cut in between. According to the author's law—all impulses from a nasal bloc to remote parts of the body must pass through the nasal ganglion and can accordingly be blocked off at that point. But under certain circumstances, not fully understood yet, when this impulse has been propelled to the same locus for a time, there develops a local pathology—a thing entirely apart from the impulse in question. The symptoms resulting from this local pathology cannot be blocked off.

Case III.—O. D. G. A business man in the forties who had had for some two or three years a set of symptoms which had been diagnosed on the one hand as appendicitis, and on the other as not. He had not been operated on. He had also had some nose symptoms and had had some kind of nasal operation performed, the exact nature of which I am not sure.

When seen he had been in bed two months with sciatica, involving the left leg, but was then able to hobble out on crutches, and it was now that he came to my office. At this time the acute pain had abated but there was quite a residue of soreness ranging all the way from the hip to the foot. Also the muscles of the leg seemed too short as he expressed it, so that attempts to straighten it out not only met with resistance but acute pain.

The left nasal ganglion was cocainized with eight per cent. cocaine with the result that the tautness of the muscles relaxed and he could then straighten the leg with ease, but the soreness did not abate. On two subsequent occasions it was blocked with the same result. Blocking the right nasal ganglion had no effect.

As I interpret this case, the impulse from the nasal bloc which had probably been of considerable amperage at first, was now reduced to relatively insignificant proportions and manifested itself chiefly through tautening the muscles. When this was blocked off, the muscles would relax. The local pathology was still at or near its height, and of course it is unthinkable that symptoms growing out of a local pathology could be blocked off at the nasal ganglion.

Case IV.—Cliff H., a negro in the thirties. Had been in bed seven weeks with sciatica when first seen, the trouble affecting the right leg. Attempts were made to block it off from both nasal ganglia but apparently without success. The cocaine applied to the right nasal ganglion seemed to make it worse if the distress could be measured by his groans. He insisted that it did make it worse. After some fifteen minutes or so it was given up as a failure. But two days later the family in which he served reported that in a few minutes after I was gone the negro was up and walking about without discomfort and that he cooked supper that night; and the next day and the next, attended to his household duties, but on the third day his pain returned, whereupon they brought him to my office.

On this second occasion it was blocked off successfully from the right side, and while the reaction was still slow, it was more prompt than the first time. Also on this second occasion he complained of the pain getting worse when the cocaine was first applied to the nasal ganglion. And as the pain began to abate he described it as "moving"—first, it was worse in the hip and then the leg, and then the foot and so on. In blocking off neuritis and arthritis I have found this not an uncommon phenomenon. As the pain begins to turn loose in one place the patient reports it as moving to some other.

At the present writing this patient is still under treatment, it having developed that he has a right hyperplastic ethmoiditis. He reports once a week for treatment, and rarely has enough pain to hinder his duties but says he has a little pain nearly every morning. About two weeks ago he got married, which may or may not have influenced the course of the case.

Case V.—Mr. P., in the forties, referred by Dr. Leffingwell. He had had sciatica off and on for four years, he said, "mostly on." A few weeks ago at a revival meeting he was healed, but had sinned again. When he came into my office navigation seemed quite difficult. I cocainized the right nasal ganglion and hardly had the cocaine been applied when he began to groan and to squirm in the chair and there is no doubt about it augmenting the pain. Then the pain began to move and soon it had abated altogether. He returned the next day still free from pain and again the right nasal ganglion was cocainized and although free of pain in the sciatic nerve in the beginning, pain soon occurred and reached proportions that he described as quite considerable but of short duration. Three days later he returned, still free of pain. This time the cocaine did not excite any pain. At this juncture he passed from observation.

This completes the series of cases of sciatica. But it was pointed out that in this group of fifty cases there were three that could not be blocked off successfully at the nasal ganglia, as follows:

Case VI.—Miss D., in the fifties. Had rheumatism in the shoulders, back, hips, and legs. The application of eight per cent cocaine to the nasal ganglia had no effect whatever on the severity of the pain. Miss D. had had gastroenterostomy done a year or so ago and still had a sensitive palpable mass in the vicinity of the duodenum. Whether that was the cause of the rheumatism I do not know.

Case VII.—Dr. G., in the fifties. Had had rheumatism, sciatica, neuritis, arthritis, "singly and separately and all together," for the lest twenty years. They could not be blocked off. There was no evidence of disease in the ears, nose or throat.

Case VIII.—Dr. N. Similar history to the above.

I do not know the source of the trouble in any of these three cases but every effort has been made to fasten suspicion on some point in the nasal blocs, but without success. So it is a reasonable conclusion that the source of trouble in these cases is in some other part of the body.

From the foregoing it is seen that there is a close relationship between neuritis, arthritis, and rheumatism. Indeed when allowance is made for differences in location and intensity, and for length of duration, all other differences seem to vanish. That some cases have their origin in a nasal bloc, and some do not, does not in any way invalidate this conclusion. But it does make it desirable, not only for purposes of interpretation, but also for treatment, to know the exact origin of any given case. The author's test when skillfully applied and intelligently interpreted is an instrument of unerring precision in determining in any given case whether it originates in a nasal bloc, and if so on which side; and the prediction is ventured that discriminating diagnosticians will come to have it used in all cases of obscure symptomatology or origin. It can be applied by any competent rhinologist.

The interpretation offered in this connection introduces a new conception into pathology—the conception of the transference along the course of nerves of an impulse of such character, and such proportions, as not only to augment a local pathology, but possibly to initiate pathological processes at the locus of registration wherever it might be.

CONCLUSIONS

From the evidence in hand the following conclusions seem imperative:

1. That disturbances arising in either nasal bloc may be transmitted to various parts of the trunk and extremities, even to the fingers and toes, and there registered in the form of neuritis, arthritis, and rheumatism, or other symptoms, but in so doing they must pass the nasal ganglion and can accordingly be blocked off at that point.

2. When such a disturbance is transmitted to the same locus for a time, a local pathology supervenes, and the pain and soreness growing out of such local lesion cannot be blocked off.

3. In a recent attack originating in a nasal bloc, and before local pathology becomes pronounced, the pain can be entirely relieved by blocking the nasal ganglion, but where the attack is of long standing, the local pathology may become the chief source of discomfort, or it is conceivable that the original disturbance emanating from the nasal bloc may be entirely withdrawn, in which case the local lesion becomes the only source of discomfort, and in that case, blocking the nasal ganglion would have no effect.

4. The author's test is a convenient and unerring method of determining in any given case of neuritis, arthritis, or rheumatism, or other obscure symptom, whether it has its origin in a nasal bloc, and also in which nasal bloc it originates.

Knee Joint Injuries—Diagnosis and Treatment*

CHARLES OGILVY, M.D., F.A.C.S.,

New York

The frequency of injury and internal derangement of the knee joint makes this subject of importance to every practitioner. Our accident insurance laws and compensation adjustment have revealed with grave significance the large numbers of these injuries which have by inadequate treatment resulted in permanent disability.

A thorough knowledge of the anatomy of the joint is the first essential in obtaining a correct diagnosis and a successful result in the treatment of knee joint derangements. The action of the joint is mainly in flexion and extension but there is also rotation and a slight degree of anteroposterior motion. The following structures of the joint, with all their ramifications and attachments, should be carefully considered:

1. The capsule.
2. External lateral ligament, which is in two parts.
3. Internal lateral ligament, which is very closely connected with the internal semilunar cartilage.
4. The internal semilunar cartilage with its two horns, anterior and posterior, widely separated from one another.
5. The external semilunar cartilage, circular in outline, with its two ends more closely together and less firmly attached than the internal semilunar cartilage, thus allowing more play when the joint is functioning, thereby being less frequently caught or injured.
6. The crucial ligaments upon which the stability of the joint in extension depends. These crucial ligaments lie without the synovial membrane.
7. The synovial membrane which "lines the deep aspect of the capsule from which it is reflected on to those portions of the femur and tibia which are intracapsular but not articular.
8. The tibial spine.
9. The tibial tubercle.
10. The posterior ligament and the tendons of the muscles which flex and extend the joint.

It is also necessary to know the relationships of all these structures, especially when the joint is functioning, in order to fully understand the result and extent of injury.

X rays should be made in every knee joint injury. It is true that when the soft structures alone are involved the x ray will be of little value in differential diagnosis. At the same time, we are so frequently surprised at the x ray findings that this rule of taking an x ray should be laid down in every instance. In this regard it may be said that gas inflation of the joint has been used to advantage in conditions of injury to the semilunar cartilage by throwing it into sharp relief and thus producing a distinct shadow in the picture. This opens up a field of interesting study.

*Presented before the New York City Hospital Alumni Society, April 16, 1924.

TRAUMATIC SYNOVITIS

The most frequent result of injury to the knee joint is a traumatic synovitis and the immediate swelling with pain and a moderate degree of limitation of motion. These are the cases in which there is no crushing, fracture or displacement of any of the joint structures. Treatment should be immediately instituted and a wet cold compress, including chipped ice in its folds, should be applied for twenty-four hours. The leg should then be put up in a plaster of Paris cast extending from the groin to the ankle and kept immobilized in this dressing for ten days. The patient may be permitted to walk the week after the accident, at which time he is still wearing the plaster of Paris cast. When the cast is removed a compression bandage is applied over a thin layer of felt. This partially fixes the joint and at the same time acts as a compression bandage. These conditions should clear up completely at the end of one month's time.

Chronic synovitis of the knee joint is the result of unsuccessful treatment of the acute form. This gives us much more trouble. The leg should be put up in a plaster dressing, as described above, and so treated from four to eight weeks, depending upon the chronicity of the condition. After the plaster cast is removed, I apply a compression bandage with a generous layer of an ointment containing iodine. It takes from three to four months to cure these conditions. If at the end of this time, however, a satisfactory result has not been obtained, I do not hesitate to open the joint through a lateral incision and after irrigation with a one to six thousand bichloride solution, inject into the joint a ten per cent. solution of iodoform emulsion.

This operation comprises a longitudinal incision to the outer side of the patella two inches long, through which an entrance to the joint is obtained.

The synovial membrane is carefully lifted and retracted with catgut strands, one on either side of the opening. After the injection of the iodoform emulsion, the synovial membrane is first carefully lifted by these catgut strands and united by a thin chromacized continuous catgut suture. The subcutaneous tissue is then sutured and the skin incision is closed with plain No. 1 catgut suture. The postoperative treatment is similar to that already described for an acute synovitis.

INTERNAL LATERAL LIGAMENT

When the injury has been associated with a definite twist or wrench, one must carefully examine for a rent or tear in the internal lateral ligament. It has been well stated that the strength of the knee joint is proportionate to the strength of the internal lateral ligament. We may also find a portion of the upper end of the tibia pulled off and still remaining attached to the internal lateral ligament. Marked tenderness over the internal surface of the joint with the excessive effusion and inflammatory reaction that follows will determine this diagnosis. An x ray will reveal whether or not any fragment of the tibia has been separated.

These conditions, also, demand immediate immobilization. If there is a separation of a fragment from the upper end of the tibia, this must carefully be cut down upon and anchored firmly in position with deeply buried kangaroo tendon, carried through holes drilled in the upper end of the tibia.

INJURY TO THE INTERNAL SEMILUNAR CARTILAGE

This is the next condition we find in frequency of occurrence. It occurs most often when the knee is flexed in weight bearing and slightly twisted. It can occur only with a tearing or stretching of the internal lateral ligament and whether or not the cartilage is injured depends upon the severity of the injury to the internal lateral ligament. It may, however, have been loosened or detached at some prior time and become displaced a second time, even while the patient is in bed, by a slight twisting of the knee without any special force or traumatism. The symptoms are those of sudden pain with a locking of the joint and inability to extend the leg fully. The patient himself may then, by maneuvring the joint about, be able to replace the cartilage in its normal position. This, however, is followed by considerable pain and excessive effusion in the joint. At other times, however, such manipulation by the patient is not successful and he appeals to the doctor for assistance. The following manipulation should then be carried out:

The leg and thigh should be firmly flexed as the patient lies upon the table. Grasping the foot with one hand and placing the other hand above the knee, at the same time the foot is rotated inward as much as possible and the patient is instructed to suddenly extend the leg with a snap. During this whole manipulation the operator assists in this manœuvre. The ability to fully extend the leg determines the success of this manipulation.

Injuries to the internal semilunar cartilage are eight to nine times more frequent than injury to the external semilunar cartilage. This is due to the firmness with which the internal semilunar cartilage is attached, in comparison to that of the external semilunar cartilage; also, the weight of the body being carried more to the inner than to the outer side of the knee joint. There follows an extreme tenderness over the site of the cartilage which is definitely prognostic. The cartilage may be split, cracked, torn, folded upon itself or dislodged. I have found a small portion of cartilage not larger than a millet seed giving severe pain with intermittent attacks of locking, pain and disability.

If after the first displacement the damaged cartilage can be reduced by manipulation and the leg extended, a fixation splint should be applied for ten days, after which a firm bandage should be continued for two weeks longer. Repeated locking or catching of the joint with symptoms of derangement of the cartilage demands operation and the removal of the cartilage as a whole or in part, depending upon the condition found.

EXTERNAL SEMILUNAR CARTILAGE

Injuries to the external semilunar cartilage are much less frequent than those of the internal semilunar cartilage, as previously stated. The symptoms are somewhat similar, however, with the difference that the pain and tenderness are all referred to the external side of the joint. The treatment is the same and the same rules hold good as to whether or not operation should be performed as in the case with the internal semilunar cartilage.

LOOSE BODIES IN THE KNEE JOINT

These are of three types: Type I. The symptoms of a loose body are those of a sudden catch with an immediate release, followed by but little pain and slight, if any, effusion. A loose body can sometimes be felt from time to time by the patient and it is not always in the same location. These loose bodies may be pedunculated and attached by a longer or shorter pedicle. They are of different sizes, ranging from the size of a pea to that of a bean. They can usually be detected by the x ray as their consistency is partly osseous. The origin of these loose bodies can often be accounted for by a previous injury, at which time a portion of the articular surface of the femur or patella has been knocked off or loosened. Those that are not completely detached may be at first small but gradually increase in size and easily become caught between the joint surfaces, giving the sudden catching so graphically described by the patient. A small portion of one of the semilunar cartilages may also be broken off and become a free loose body in the joint. Otherwise the joint is found to be normal. The only satisfactory treatment of these loose bodies in their removal by operation.

Type II. Multiple loose bodies, usually two or three in number, may result from a pathological condition, such as tuberculosis or other of the arthritides. There are usually two or three in number, seldom more. They are derived from the femoral and patellar surfaces in most cases. They are mostly cartilaginous but they also may contain small bony deposits.

Type III. Another type of multiple loose bodies found in the joint are those chondromata which develop in great numbers. Several hundred of these

may be found in the joint. These are derived from the synovial villi and are pedunculated or free. They may lie for a long time in the recesses of the synovial chamber without giving any trouble until they are dislodged. They range in size from a millet seed to the size of a bean. They are of the same structure as the last described and are usually much smaller in size, but they occur in larger numbers. They may develop also from the infrapatella fat body. The primary injury may cause a breaking through of a portion of the fat body and repeated injuries to this result in a cicatrization and hardening of the pedunculated mass or masses, which in time become detached.

INJURY TO THE CRUCIAL LIGAMENTS

This follows only after severe injury to the knee joint. The anterior crucial ligament is much more liable to injury than the posterior and as a matter of fact, it seldom happens that the posterior crucial ligament is involved, except in those cases associated with complete dislocation of the knee. It frequently happens in severe injuries that both the internal semilunar cartilage and the anterior crucial ligament are torn. With the loosening of the anterior crucial ligament there is a greater range of abduction in a semiflexed position. Hypermobility of the joint is very apparent and this is noted best with the knee in full extension. Internal rotation of the tibia on the femur with the knee in full extension is also considered an important diagnostic point by Sir Robert Jones in injury to the crucial ligaments. There is also with the overstretching of the anterior crucial ligament a certain amount of lateral rocking of the joint. The treatment of the injuries to these crucial ligaments is immediate immobilization, which should be continued for two months' time. Gradual motion is allowed after this, but the convalescence is necessarily long and tedious. The question of operation should be considered in these cases but conservative treatment has so far proved more advisable in the majority of cases.

AVULSION OF THE TUBEROSITY OF THE TIBIA

This occurs in youth and results in a separation, partial or complete, of the tuberosity from the tibia with associated signs of tenderness and inflammation over this area. Pain is felt over the insertion of the patella tendon. The symptoms may not be severe and may run a more or less chronic course. X ray findings will give corroborative evidence of the diagnosis and should the separation of the tuberosity be complete, and if it is pulled some distance from its attachment to the tibia, operation will be necessary. This, however, is seldom the case and fixation and rest are usually sufficient to relieve the condition.

AVULSION OF THE TIBIAL SPINE

This occurs in some cases of severe injury associated with or without a rupture of the anterior crucial ligament. When this happens, the main point in diagnosing is that the displaced spine prevents full extension of the joint. It is true that the same diagnostic symptom has been mentioned in relation to displaced internal semilunar cartilage, but in the first instance it is a bone block and in the case of the cartilage it is a soft cartilaginous block which can readily be distinguished from bone. An x ray will corroborate the diagnosis. If recognized immediately and treated by immobilization after reduction, the prognosis is good. In older cases where the fragment still obstructs the joint in extension, it may be removed from excellent results. When it is associated with the rupture of the anterior crucial ligament, the prognosis is not so favorable.

ARTHROTOMY OF THE KNEE JOINT

When an arthrotomy of the joint is demanded for any internal derangement of the knee joint, the two following operations commend themselves. Both of these have been devised by Sir Robert Jones. First, entrance into the joint laterally; second, entrance into the joint through the patella.

If there is no doubt as to the exact condition present and that it refers definitely to the internal semilunar cartilage or the inner surface of the joint, we may enter the joint laterally. "A tourniquet is applied to the thigh, and the leg to be operated upon is flexed over the end of the table. With the knee flexed at a right angle, a curved incision is made two inches in length. The incision, which involves the skin only, begins one fourth inch internally to the inner edge of the patella at its center. The cut curves downwards and backwards for one inch until it reaches the level of the joint and for the remaining inch it runs parallel to the upper articular surface of the tibia. Great care is required not to prolong this incision so far posteriorly as to endanger the anterior fibers of the internal lateral ligament. The joint is opened and two small retractors separate the line of incision into the synovial membrane." An inspection can now be made of the joint structures at their inner portion, the semilunar cartilage examined, broken portions of it removed, or the entire cartilage may be dissected away, if it is deemed advisable.

THE INFRAPATELLA ROUTE

The infrapatella route, or the split patella route, is the operation of choice whenever a thorough examination of the whole joint surface is desired, including, as it should, the crucial ligaments. It is peculiarly adapted to those cases which give rather an indefinite history of the location of the derangement, as it has not infrequently happened that the external semilunar cartilage has been involved and only the internal semilunar cartilage was suspected. In operations for loose bodies also, these are much more easily found by the exposure obtained through the split patella route. A tourniquet having been applied, the leg hangs over the end of the table, and a long curved incision beginning two inches above the patella and extending down almost to the tibial tubercle is made through the skin and subcutaneous tissue. The patella, standing out in bold relief as it does, is now sawn through its center longitudinally, either with a motor driven or hand saw, through almost its entire thickness. With a thin bladed ostetome the separation of the two fragments is completed. The quadriceps extensor tendon is now split upwards to a point two inches above the patella and the patella tendon is split one inch downwards toward the tibial tubercle. Through this opening, by means of retractors, a very good view of the joint is now obtained. After the operation within the

joint is completed, the tendon of the quadraceps extensor is carefully drawn together with chromacized catgut or fine kangaroo tendon, as is also the patella tendon. The cut periosteum and thick fibrous tissue over the front of the patella is now closely united along its edges by a continuous chromacized catgut suture, thus closely approximating the cut surfaces of the patella. No further suturing of the patellar fragments is necessary.

The postoperative treatment of both of these operations consists in immobilizing with plaster of Paris, followed by passive motion and massage and subsequently active motion and weightbearing. The length of time, however, differs in each instance. In the first, at the end of one week, the fixation splint is removed, massage is begun and slight active and passive motion instituted. At the end of the third week the patient should be allowed to walk with freedom and have full range of motion.

In the case of the split patella operation, fixation in splint is continued for two weeks, after which time active and passive motion is begun and patient gradually begins function of the joint, both in motion and weightbearing, being able to walk freely at the end of five weeks' time.

FRACTURES OF THE PATELLA

Fractures of the patella, with few exceptions, should be operated upon. There is little danger in the operation and an operation guarantees a good bony union, whereas otherwise the best result usually obtained is that of a fibrous union. The best operation for fracture of the patella is that of encircling the bone by two circular kangaroo tendons, one introduced on the outer side of the patella, running about its margin and coming out at the same side; the second being introduced at the opposite side, being passed about the circumference of the bone and coming out again on this opposite side. These two sutures are then at the same time drawn firmly together, thus bringing the fragments of bone in very close apposition and being held firmly in place by strong kangaroo tendon which remains unabsorbed for several weeks, giving sufficient time for good bony union to take place.

This operative procedure is applicable for all kinds of fractures of the patella. After operation the limb is encased in plaster of Paris and active and passive motion is begun in three weeks' time.

CONCLUSION

In closing, I wish to state that one of the greatest advances in surgery during the past decade has been in the field of operative technic upon the knee joint. The old idea that the knee joint is particularly prone to infection has been proven to be quite erroneous. In fact, it may be said that this joint possesses particular powers of resistance which enable us, with proper technic and aseptic precautions, to enter it without hesitancy. The results that are being obtained today in relation to operative treatment of derangements of the knee joint are most excellent and many types of cases heretofore relegated to permanent disability are offered a very favorable chance of perfect recovery.

Operative Treatment of Osteomyelitis in Long Bones

W. H. HALLILAY, I.M.S.,

London

Of all the surgical operations practised at the present time, probably the most unsatisfactory to patient and surgeon alike are those undertaken for the relief of chronic bone disease, especially for chronic osteomyelitis of long bones. The history of such cases is usually a depressing one, consisting of an account of continuous or intermittent suppuration from a persistent sinus or sinuses varied by the recurrence of acute trouble followed by operation and inevitable disappointment. After one of these interludes of pain, insomnia and fever, the flow of pus resumes the even tenor of its way.

These cases may persist for years, from childhood to adolescence and through adolescence far into adult life, unless a more than usually severe exacerbation of sepsis or the onset of amyloid disease, ends the patient's troubles by cutting short his or her life.

Many of these mournful legends are illustrated by pathetic ossuaries, fragments of necrosed bone which the sufferers have collected as melancholy souvenirs of epochs of intenser suffering in a life time of discomfort. They will relate how on this, that or another occasion the bone was "scraped." Some of these scrapings were so obviously futile that the listener is reminded of Sydney Smith's famous remark to the little girl who told him that she was stroking the back of her tortoise to tickle it. He said, "you might as well stroke the dome of St. Paul's to tickle the Dean and Chapter."

The surgical problem is that of a septic cavity with rigid walls; many attempts have been made to solve this problem, some along the lines followed by a dentist, when dealing with a cavity in a carious tooth, by introducing an amalgam of metals as a filling, others have used calcified sponge. Some have employed antiseptic pastes which introduced hot sets solid on cooling. Others have attempted to obliterate the cavities by means of pedunculated grafts of muscle, a procedure obviously doomed to failure in the presence of any residual sepsis in the bone cavity. The success attending these methods are, on the whole mediocre, but they all have one aim in common, the obliteration of the cavity in the bone.

The method to be described has this object in

Fig. 1.—Case III, H. S.

Fig. 2.—Case III, H. S.

view, but attains it not by the introduction of a foreign body into a cavity, but by the conversion of the cylinder of bone into a lath, nothing but the posterior thickness of the shaft being left. The free removal of all overhanging bone permits the periosteal sleeve to collapse upon the residual strut of bone. New bone is laid down from the adjacent surfaces of shaft and periosteum.

TECHNIC

The conservation of the periosteum is essential in this operation. The incision is made on the surgical aspect of the bone, down to the periosteum for the whole length of the diseased area; the periosteum is then carefully separated from the bone by means of a rongeur; this should have a chisellike edge so that an abundant supply of bone cells from the cambium layer is elevated with the periosteum. The subsequent rate of repair will be directly influenced by the care with which this operation is carried out. The periosteum is separated up to the limit of the bone which it is decided to retain, always remembering that it is necessary to continue the removal of bone until nothing is left but the two plane surfaces of the posterior aspects of the bone.

It is hardly necessary to say that with the most ordinary care, by working within the periosteal sleeve, the danger of the damage to soft parts is negligible. As soon as sufficient of the bone has been stripped the anterior aspect of the shaft is removed by suitably planned cuts into the bone. This may be done with an Albee saw or with chisel and mallet as desired. The saw saves much time and labor but the necessary trimming of the residual shaft may be effected by means of chisel and gouge. The surface of the bone which remains is carefully scrutinized for grey areas of necrosis, or for sinuses or actual perforations and all disease tissue is energetically removed.

It should next be ascertained how far the periosteum and soft parts will glide over the remaining shaft of bone. Any projections interfering with this should be removed as it is important to reduce the number of dead spaces to a minimum.

When the operative area is in the neighborhood of a joint great care must be exercised to avoid damage to the articular cartilage and the bone should be shaped so as to avoid a steep descent from the neighborhood of the joint. This is particularly necessary when dealing with the tibia as if too steep a gradient is allowed it will be difficult to get the raw surface of the bone covered by the flaps of soft tissue and periosteum. When all the diseased tissue has been removed we have a sort of keel of bone to which is hinged on each side a flap of periosteum originally covering half the expanded shaft and preserving its original connections with the soft parts in relation to the bone, and in consequence of maintaining its blood supply intact. These flaps are united over the line of the original incision by interrupted silk worm gut sutures. This brings about the abolition of nearly all the dead space, any space left at the upper extremity of the bone being carefully plugged with gauze and allowed to fill up from the bottom.

If all diseased tissue has been removed such cavities will become obliterated by a vigorous growth of fine healthy looking granulations and the discharge will be no greater than that of any other healthy granulating surface. Increase of or persistence of purulent discharge usually means some undetected focus of caries or recrudescence of caries in some part of the bone; these always indicate subsequent minor operative proceedings.

The following cases will illustrate the method; if the solidity of the bone permits the patients should be allowed on their feet at the earliest moment; use is the greatest stimulus to bone growth.

Fig. 3.—Case III, H. S.

Fig. 4.—Case III, H. S.

To secure success and rapid healing, the surgery must be very bold and very radical. Half hearted operations are better left undone.

ILLUSTRATIVE CASES

Case I.—P. S., aged twenty-eight, duration of disease one year. Admitted May 2, 1923. History of much pain and disability in leg.

Operation June 10, 1923. Great thickening and sclerosis of bone and caries in medullary canal—extending nearly half the length of the shaft. Complete operation—removal of all but a lath of bone—so that no overhanging edges were left—the separated leaves of periosteum came into good contact with the denuded bone.

His convalescence was uneventful—and there was abundant formations of new bone. The wound healed by first intention. Discharged July 28, 1923. Total time in hospital after operation twenty-one days.

Case II.—I. D., aged twenty-two. Necrosis—chronic osteomyelitis of right tibia. Leg riddled and suppurating sinuses—duration ten years. Admitted July 3, 1923.

Operation July 9, 1923. Complete operation. Bone much sclerosed and thickened. Rarefying osteitis in medullary aspect—pus—no massive necrosis—no involucrum. All bone removed in anterior and lateral aspects, only a lath of bone left behind. The periosteum was carefully conserved.

One small secondary operation was found to be necessary. The lower half of the wound healed by first intention, but there was a small cavity left at the upper end which was not quite healed when the patient left the hospital on October 3, 1923. Stay in hospital June 21st to October 2nd.

Case III.—H. S., aged twelve. Much discharge, massive necrosis and involucrum. Admitted July 30, 1923. Operation July 31, 1923.

Complete removal of all but post layer of involucrum, cylinder of necrosed shaft removed—it was lying free—periosteum came into good contact with denuded area—healed by first intention lower half wound. A cavity which was left in the upper part was plugged and granulated up. Discharged February 24, 1923. Stay in hospital fifty-five days.

Case IV.—J. R., aged twelve—left tibia. Chronic osteomyelitis. Duration—6/12. Admitted June 4, 1923. Necrosed sinus—sequestra—foul and copious discharge. General health very poor.

Operation: June 12, 1923. Sequestra removed. All but posterior part of bone removed. Periosteum in good contact with denuded area in lower two thirds of wound. Cavity left in upper part—which was plugged—on August 21, 1923—the upper part was explored and a large piece of old necrotic stuff found under edge of an overhanging ledge of bone. This was chiseled away, the piece removed and all granulations removed at the same time. Packed with gauze, wound securely healed in its entire extent by November 10, 1923, when patient was discharged. General condition was much improved.

Case V.—A. H., aged fifteen, chronic osteomyelitis of ulna. Duration one year. The ulna border of the arm was riddled with sinuses, much discharge, sequestra. Admitted June 30, 1923. Operation: July 10, 1923—large sequestra round rather patchy involucrum, many sinuses, bone removed so as to have plane surface of bone—periosteal sleeve came into good contact with the denuded area. Discharged August 29, 1923. Good formation of bone and wound soundly healed.

Rational Treatment of Fractures in the Region of the Elbow Joint

SAMUEL W. BOORSTEIN, M.D., F.A.C.S.,
New York

The elbow is a very important and also a very complicated joint. While the shoulder region is also complicated and essential, performing so many necessary functions, still the scapula can often serve as a substitute in performing these functions. The elbow joint, on the contrary, has no substitute. The two joints, viz., the humeroulnar and the radioulnar, have the responsibility of earning our livelihood and also feeding us. Justly does Jones (6) say: "Any defect in the muscles, ligaments, or articular surfaces connected with these movements is so annoying to the patient that he declares that they make this joint practically useless."

One notes with great regret that proper treatment of this joint is very often neglected. The blame may justly be charged to one or both of two factors. 1. This injury does not confine the patient to bed, hence he is not taken to a hospital where proper and expert treatment can be instituted. Consequently, the case is treated in a dispensary with its hustle and bustle, by a general practitioner, or by a layman (bone setter). The result, therefore, can not be compared to the fractures of the lower extremity. 2. If the fracture is one that may result in a deformity at the knee or thigh, the patient or his relatives could easily observe it and conclude that it will interfere with proper function. The fractures of the upper extremity, with the exception of the wrist joint, on the contrary, do not exhibit the deformity so prominently to the patient, hence he himself is hopeful that the result will be good. He is thus satisfied with less specialized treatment for this essential joint than he would choose for the lower limb.

Sir Robert Jones (6) has greatly simplified the understanding of the fractures in the region of the elbow joint with his emphatic precept: "There is one golden rule regarding fractures of the elbow; they should all be treated with the elbow fully flexed and the forearm supinated, with the single exception of fracture of the olecranon, which requires full extension." Many surgeons state on their operation charts that the fracture was put up in the Jones posi-

FIG. 3.—Case II, S. H. Showing marked displacement and rotation of the lower fragment.

tion but how many are put up in the real Jones position?

POSITION

The proper position is only of secondary importance; the aftertreatment is, as in all fractures, of paramount value and must be accurately carried out. The failure to obtain good results in this fracture can often be justly traced to the neglected aftertreatments. Whether one believes in early massage or late massage, active or passive motion, no rule can be strictly adhered to in this region. One must use a combination of methods.

Discussion of this fracture which falls so often to the lot of the general practitioner should be of great interest.

MECHANICS OF THE FRACTURE

For our purpose it is sufficient to state that: "Fractures of the humerus in the vicinity of the elbow joint may be caused by direct or indirect violence. If an adult falls on an outstretched arm and sustains a fracture, it is usually a fracture at the base of the radius (often a Colles); if a child, the fracture usually occurs near the elbow. Therefore, the rule can be laid down that a fracture of the elbow in a child is almost always due to indirect violence transmitted through the hand and forearm to the elbow with the arm hyperextended, while the same type of injury in an adult is usually due to violence applied directly to the elbow region." (Gilcreest (4))

RADIOGRAPHIC STUDIES

It is essential to take a radiograph of the normal limb. In children the radiograph is frequently misleading, hence Baetjer and Waters (1) emphasize "In injuries of the lower end of the humerus in young children care must be exercised in making a diagnosis of no fracture. We must bear in mind that a great portion of the joint is cartilaginous and that a fragment of cartilage may be broken off and yet not be demonstrable by the x ray. In such cases it has always been the custom of the writers to return a diagnosis stating that no fracture can be demonstrated."

PROPER TREATMENT OF FRACTURES OF ELBOW JOINT

In a previous article (2) I summarized, in general, the modern treatment of fractures which will of course apply likewise in this case. Some of the conclusions are as follows:

1. Proper attention should be paid to treatment of fractures, as better and quicker results are now expected.
2. Early reduction is absolutely necessary.
3. Reduction should be performed with full consideration of muscle pull and not according to the traditional custom of pulling by direct extension.
4. When possible, the fracture should be reduced under the fluoroscope.
5. Restoration of anatomical position should be the aim, but partial lateral displacement or impaction without alteration of the axis of the limb is allowed.
6. Prolonged immobilization is harmful.
7. Massage should be commenced very early, about the third or fifth day; but it must be administered very carefully and gently in the hands of an experienced masseur.
8. Active exercises are preferable to passive. These should be commenced early, as they prevent stiffness and adhesions. They never cause pseudo arthrosis.
9. Passive exercises may be justified only at the end of the treatments to obtain full range of motion, but even these should be done gently.
10. A röntgenogram should be taken before and immediately after reduction, and at frequent intervals during the course of treatment. The patient should not be discharged without a final röntgen ray examination.

METHOD OF REDUCTION.

1. *Fracture immediately above the condyles.*—For all fractures of lower end of humerus we may quote Sir Robert Jones from his excellent book (6) as the language cannot be improved on.

"The best means of reduction—I would almost venture to say the only means of complete reduction—is a combination of complete flexion of the elbow with downward traction of the forearm. If the limb

is then bandaged in complete flexion, with the forearm supinated, i.e., the palm towards the shoulder—a good result in every case of simple uncomplicated fracture is practically assured. The tendon of the triceps muscle arranged like a strap round the back of the joint is a perfect splint. The coronoid process

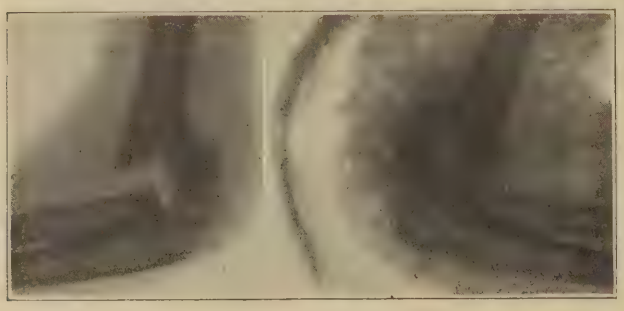

Fig. 4 Fig. 5

Fig. 4.—Case II, S. H. Position obtained after the operation; hand in cast.

Fig. 5.—Case II, S. H. Six weeks later showing the union of the lower fragment and the prominence of the upper fragment. A. Anteroposterior view. B. Lateral view.

of the ulna tucked into the coronoid fossa steadies the lower fragment in front. No excessive callus can form in front to form an obstruction, because there is no room for it."

2. *Fracture of condyles involving the joint.*—"Reduction: The surgeon takes the lower end of the humerus in one hand with the thumb above one condyle and forefinger above the other—the elbow is thus in his hand. With his other hand he pulls the forearm in the line of the limb and gently but resolutely brings the elbow into full flexion with the forearm in full supination. While performing this movement the hand grasping the condyles feels any movement that takes place among the fragments, and by following that movement by gently grasping them they can usually be coaxed into better apposition. Flexion must be resolute so that any fragment displaced forward is pushed aside out of the way. If any fragment is lodged in front of the joint and blocks full flexion, it should be replaced and fixed by operation should manipulation fail." (6)

It is absolutely necessary to look out for the preservation of the carrying angle[1], therefore there should be slight abduction of the forearm particularly in cases of fractures of the internal condyle. In some cases where it is hard to obtain good position by traction on the flexed elbow I have exerted at first traction on the forearm with the elbow fully extended and supinated. The joint is manipulated at the same time and the displacement corrected. The elbow is then slowly and firmly flexed to an acute angle. The hand of the surgeon must be kept on the lower fragment of the humerus.

DIRECT REDUCTION

If proper facilities are available the fracture of course should be reduced under the fluoroscope. Eliason says: "The anteroposterior deformity is first reduced, the forearm flexed and the fluoroscope used with the arm and forearm abducted and in the plane of the supine patient's body. If this view is good, the limb is brought to the patient's side with the hand on the shoulder of the injured side and a look taken. Should there be lateral displacement the forearm is extended to about a right angle and the lateral deformity corrected" (3). Retentive apparatus is then applied. The methods of reduction by complete flexion or extension can of course be carried out very easily under the fluoroscope. "In fractures of the elbow joint where sepsis is present, it is often useful to put the supinated arm in full extension and fixation in a Thomas arm splint until the acute sepsis has been controlled or the fracture has begun to show signs of union. Nearly always, even finely comminuted fractures, in which we know a large part of the fragments are absolutely detached, if not infected, unite very rapidly, forming a large callus. The arm should then be gradually flexed, maintaining the supination. It is unwise to leave the arm extended more than one month for fear of bony ankylosis in this awkward position." (4)

RECAPITULATION OF REDUCTION OF FRACTURES OF LOWER END OF HUMERUS

1. Supracondylar fracture of the elbow downward traction of the flexed forearm; if not successful may try elbow in hyperextension.

2. T fracture into the joint—traction on the forearm in the line of the limb and then gently bringing the elbow into full flexion with the forearm in full supination.

3. In fracture of the internal condyle or even the supracondylar there should be slight abduction of the forearm to preserve the carrying angle.

Fractures of neck of radius.—These are put up in full flexion with the forearm supinated. If it is dislocated as well as broken off it usually impedes free flexion and may have to be removed. Many surgeons therefore resort to early operation. The lump of callus which forms round the broken end of the neck forms an excellent head under the molding forces of the ordinary movements of the part. One should, however, at first try to reduce and immobilize it before resorting to an open operation.

Fracture of the olecranon process.—If there is no displacement of the upper fragment, the elbow is put in full extension. It is advisable to put on a firm

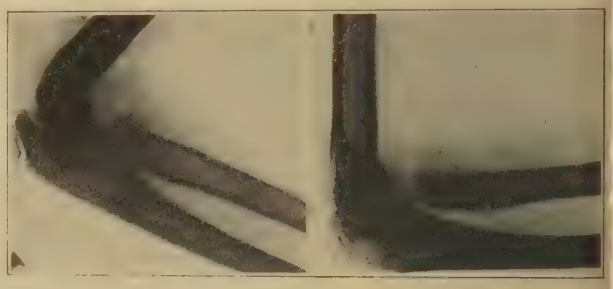

Fig. 6 Fig. 7

Fig. 6.—Case III, V. C. Fracture of head of radius. March 23, 1923, before treatment.

Fig. 7.—Case III, V. C. Showing good position of head of radius, June 2, 1923, when patient was discharged.

pad from felt above the olecranon to stop the triceps from moving it upward. A plaster cast from the axilla to palm is applied. If there is a displacement of the upper fragment—it is a clear indication that the biceps has already contracted and pulled the fragment upward. One may try at first to replace the

[1]The carrying angle is the term applied to the angle made by the forearm in its attachment to the arm. In male this is about ten degrees, while in females it is between fifteen and twenty degrees.

fragment and then to immobilize it but it is doubtful whether it can be done. It usually requires an open operation and the fragments fixed into position; kangaroo tendon will often suffice.

PROPER RETENTIVE APPARATUS

Adhesive plaster can be used or as in some cases a Thomas arm splint or Jones humerus splint can be used, an aluminum internal angular splint or a bandage and sling. I personally am a strong advocator of application of a circular cast. I believe that in the hands of the experienced it makes the best splint. It holds the fragments well, it prevents the swelling and is the most comfortable apparatus. It can certainly be applied in such a way as not to interfere with the circulation. It can also be split later into two halves when the time for massage and active motion comes; the upper or anterior part be thrown away while the posterior one used as a splint. The plaster extends from fingers to the axilla. Jones (6) warns against the right angular splint as follows: "A warning must be given against the old right-angled internal splint for the elbow. Satisfactory use of this splint is extremely difficult. Distortions about the elbow are frequently produced by its use, and it is therefore to be regarded as a dangerous device.

"First, it provides no easy means of preventing backward displacement of the lower fragment. Second, it leaves room for the formation of excessive callus in front of the elbow. Third, it is very easy with this splint to press unduly on the internal condyle, tilting the lower fragment outwards and so throwing the joint out of true alignment, and this condition may not be noticed till the patient begins to use his arm—it is therefore an insidious danger. We may therefore say that the internal rightangled splint for treatment of elbow-joint injuries is to be regarded as absolutely obsolete." I have therefore abandoned the anterior angular splint.

Some still cling to the use of adhesive plaster as a retentive means. A word of warning should be used. The adhesive plaster must not be put as a circular band around the upper end of the acutely flexed elbow, as there is produced a sharp constriction of the flesh by the upper edge of the strap. The strap must be laid flat on the skin. The ends must therefore meet at an angle and pinned as well as stuck together.

AFTERTREATMENTS

As mentioned before, the good results can be obtained only if the aftertreatments are properly carried out. It must be begun early, best on the fifth day. If one is too cautious he may postpone it three days longer. Active motion should be begun at the same time or at least on the seventh day. It is carried out as follows: The dressing is removed, the masseur carefully holds with one hand the fractured bones and orders the patient to drop the elbow a few degrees, then to be flexed to the former position. This is repeated twice. The following day the voluntary range of motion is increased. In about a week one usually finds that the patient can reach to a straight angle; the splint can then be changed for one of a right angle and used part of the time as a retentive apparatus. The first splint which forced the elbow into flexed position is also kept on for part of the day. The cast can be discarded at the end of three weeks and a sling substituted.

MOVEMENT

During the process of active motion, should the elbow stiffen so that the patient can not obtain the initial degree of flexion, all movement should be discontinued. It indicates that the repair is not far enough advanced to allow movement without damaging the site of repair. The arm should again be put in complete flexion for one week, then active motion resumed.

Passive movement should be commenced in the fourth week and should consist of only one movement in each direction (pronation, supination, flexion, and partial extension) and then replaced in the cast. The fracture should be protected by the surgeon's other hand while the passive motion is carried out. If the passive motion produces much pain, it should not be repeated for several days.

COMPLICATION OR RESULTING DEFORMITIES

1. *Volkman's contraction.*—The possibility of this complication in fractures of the elbow is rather frequent in inexperienced hands and should always be kept in mind, particularly in children. It can be prevented, first, by having no pad in the elbow; second, having no constricting band or bandage about the joint, and third, seeing that the angle of flexion is not too extreme.

2. *Traumatic myositis ossificans.*—This is very common in dislocations but may also be found in fractures.

3. *Ulna nerve or median nerve injury.*—While this injury is usually due to involvement in the callus, it may occur many years later, and may require neurolysis to free the nerve. If severed at the time of fracture, of course it should be sutured. Discussion of the treatment of this complication is out of the scope of this paper.

4. *Nonunion.*—Discussion of nonunion is out of the sphere of this paper and need not be discussed, as the same rule applies here as in all fractures.

5. *Fibrous union.*—In some fractures, as in either condyle, or olecranon process or epicondyle or head of radius, fibrous union is not so dangerous and patient can have a useful limb. Where the fibrous union weakens the bone operative procedure may have to be considered.

6. *Malunion.*—In malunion the flexion is often limited by a piece of bone in front of the elbow, usually arising from the lower end of the upper fragment. In such cases we can easily remove that by an open operation. Where there is a cubitus valgus increase of carrying angle (as a result of fracture of external condyle) or a traumatic cubitus varus (commonly called gunstock deformity)—diminished carrying angle (due to a fracture of internal condyle or intracondyloid fracture of the humerus)—an osteotomy of the humerus on the desired side will correct them.

7. *Ankylosis of the elbow joint.*—Due to proximity of the joint, fibrous or bony ankylosis of the elbow joint may result.

Where there is stiffness of the elbow joint due to adhesions, the question of breaking up the adhe-

sions arises. Jones and Lovett (7) summarize that as follows: "Manipulation of the elbow joint requires more care and judgment than does that of the shoulder and should always be gentle. If the adhesions are light and there is no injury to the joint, it is only necessary to flex and extend completely with the arm first in complete pronation and again in complete supination. In this way adhesions of the radioulnar articulation are simultaneously overcome. If adhesions, however, are firm and limitation of movement is marked, as is often the case in old fractures, the elbow should be gently extended in supination and then flexed to the point of safety and fixed in this position by a sling for a few days. It should then be extended and fixed in extension for no longer than two days. The arm should then be freed, and active and gentle passive movements practised, the fracture, if present, being protected from strain by splints. It may be necessary to repeat the movement in a few days.

Where the stiffness of the joints is due to bony ankylosis, an arthroplasty is advisable.

REPORT OF A FEW INTERESTING CASES

In illustrating some of the principles explained above, I shall not take up the ordinary cases where the result was perfect function in a short time, as every surgeon can report many such cases. I will take up only difficult ones, show the complications, and then point out the final result.

Case I.—G. S., male, aged six and a half years, came to me on May 25, 1923, referred by Dr. Goodside. Four days before he had sustained a dicondylar fracture of the left elbow with displacement of the lower fragment backward. (Figs. 1 and 2.) The elbow was markedly swollen and painful. Reduction was performed and a plaster cast applied. Aftertreatments were begun in three days. There were marked adhesions interfering with the free motion of the joint so that about six months of active and passive motion were necessary before the patient obtained good function. There was, however, ten degrees limitation to complete flexion, while extension was perfect.

Comment: The adhesions in this case were probably due to the delay in the reduction giving a chance meanwhile for the extravasated blood and torn muscles to form adhesions.

Case II.—S. H., male, aged eleven, was referred by Dr. Friedland on July 11, 1923. The patient had a T fracture of the right elbow joint (thirteen days' duration). He had been treated before with a right angular splint, but the x ray showed poor alignment and twisting of the outer condyle and also some tearing of the periosteum on the posterior aspect of the humerus. (Figs. 3, 4 and 5.) The elbow joint was markedly swollen obliterating all landmarks and one could feel the lose fragments.

Under anesthesia and the fluoroscope the forearm was extended, then by slow traction the fragments were dislodged and manipulated and the forearm gradually flexed. The elbow was brought to an angle of 70° with the forearm supinated. A plaster cast was applied. The x ray showed much better position. Aftertreatments were instituted five days later. It was some time before the motion returned but the final result was very good.

Comment: In a complicated fracture like that, one could not expect a good result especially when it had to be reduced thirteen days after the occurrence. Under the fluoroscope, however, the fracture was reduced and by putting the arm in acute flexion, perfect function resulted.

Case III.—V. C., female, aged twelve, was referred by Dr. Messemer. There was fracture of the head of the radius of one day's duration. (Figs. 6, 7.) The forearm was put in acute flexion, and baking and massage instituted five days later. A perfect result was obtained in three months.

Comment: Judging by the size of the fragment one could expect that an open operation to remove the head would be absolutely necessary. However, the acute flexion placed the head in good position and thus a good result followed.

CONCLUSIONS

1. Fractures in the region of the elbow joint are serious on account of disability that may follow improper treatment of this important joint.
2. These fractures should be treated properly from the very beginning as interference with function usually results.
3. They should all be treated with the elbow fully flexed and the forearm supinated, with the single exception of fracture of the olecranon, which requires full extension.
4. Immobilization can be obtained by means of adhesive plaster, bandage and a sling, an aluminum internal angular splint, Thomas arm splint, Jones humerus splint and plaster of Paris cast.
5. The aftertreatments should be carefully and intelligently carried out and not left entirely to an ignorant masseuse or to the judgment of the parents.
6. Massage, baking, and active exercises can be begun in the first week.
7. Adhesions present should be broken up with great care.

I wish to thank the surgeons of Fordham Hospital for their kind co-operation in this work.

Practical Points in the Diagnosis and Treatment of Fractures*

HENRY KELLER, M.D.,
New York

A fracture may be defined as a solution of continuity of bone and can be divided into two general groups: fractures of the diaphyses and fractures of the epiphyses.

In diaphyseal fractures the false point of motion is more evident than in epiphyseal fractures; there is a tendency in the former to overriding and shortening, which is most marked in the case of single bone regions, i. e., humerus and femur. In epiphyseal fractures the articulations are frequently involved.

The causes may be divided into those which predispose the bone to the strain which can result in solution of its continuity, and exciting causes are those producing the actual break.

1. Predisposing causes are functional, external influences, pathological, intrauterine or obstetrical.

2. Exciting causes are muscular action and external violence, either direct or indirect.

The bones as the rigid framework of the body must take up the stresses and strain transmitted by the muscles and ligaments which come in ordinary exposure and daily work of life. The structure of bone, though being normally adopted to these necessities, will give way when its limit of elasticity is passed, and fracture will result. Pathological invasions affecting the human skeleton, or part of the skeleton, may reduce the normal elasticity to a minimum, and result in loss of resistance of the bone to the slightest strain.

In discussing external influences as a predisposing factor in fractures, Speed gives a very interesting summary, supported by statistics taken from the Cook County Hospital of Chicago, thus: "Other predisposing causes arise from outside influences incident to occupation, such as, sex, age, season, and exposures of life. Occupation and sex are closely intermingled, because males as a rule perform the hardest labor and are occupied in more dangerous work.

In a consecutive series of 10,702 fractures studied at the Cook County Hospital, there were 7,954 closed fractures, and 399 open fractures in males, and 1,154 closed and twenty-seven open fractures in females. The remainder were in children."

INTERPRETATION OF SYMPTOMS OF FRACTURE

In order to properly interpret the various symptoms and signs which are usually associated with the presence of a fracture, one must bear in mind that, though a fracture is defined as a "solution of continuity of the bone," it is usually accompanied in the majority of instances by an injury to the soft tissues as well, which is of more importance than the fracture of the bone itself, and as Estes points out correctly that "in no instance, except perhaps, in the rare cases of socalled groenstick fracture, may the soft tissues be forgotten or neglected in treating the case."

The five cardinal diagnostic points which are laid down in every textbook are: Pain, loss of function, deformity, false point of motion, and crepitus.

One must bear in mind that symptoms are subjective, while signs are objective. The subjective reactions which we term symptoms depend a good deal upon the age, sex, social status and temperament of the sufferer, and should therefore be accepted with a critical mien.

Hence pain which is looked upon as one of the most important, if not the most important in the diagnosis of fractures, must be carefully scrutinized before full reliance can be placed on it. Loss of function may be due to the injury or may also be due to hysteria, or exaggerated responsive reflexes causing suspension of normal function of the limb. As for deformity and false mobility, the physician must ascertain whether or not there was any presence of a deformity prior to the injury. Crepitus is of great importance, but one must differentiate the grating of a blood clot accumulating around the injured part from real bony crepitus. In marked overlapping of fragments, crepitus is usually not obtainable. Nor in marked separation of fragments, as in the patello and olecranon. It is also absent in impacted fractures and in incomplete fractures.

FREQUENCY OF FRACTURES AS TO LOCATION.

A radiological analysis of 1,226 cases made by C. R. Scott as to location gave the following results:

	Per cent		*Per cent*
Skull	7.01	Pelvis	2.93
Vertebræ	2.11	Femur	10.44
Humerus	4.89	Fibula	13.53
Radius	8.80	Tibia	14.92
Clavicle	3.26	Tarsals	3.18
Scapula	1.38	Metatarsals	3.18
Ulna	7.01	Phalanges	2.28
Carpals	0.97	Patella	0.89

FRACTURES FREQUENTLY OVERLOOKED

There are three locations in the body, which are exposed to fractures quite frequently, and which to my amazement are overlooked in ninety per cent. of cases, namely: fractures of the neck of the femur, fractures of the vertebræ and appendages, and fractures of the os calcis.

It is indeed amusing, though tragic, to see how many diagnoses are put down for these conditions. Fractures of the neck of the femur are usually diagnosed as dislocations of the head of the femur, sprain of the hip is another favorite diagnosis with many. Rheumatism is another diagnostic term to cover the physician's ignorance.

It is my experience that ninety per cent. of fractures at the neck of the femur are not diagnosed early enough to give the orthopedic surgeon the opportunity to institute immediate treatment, which is, after all, the only way by which a perfect result can be anticipated.

Year after year hours are being spent at the state and national medical and surgical gatherings, in discussing fractures of the neck of the femur, with particular emphasis laid upon the various methods

*Paper read before the Clinical Society of the West Side Hospital Dispensary, New York, May 21, 1924.

of treatment with new devices and new apparatus, as well as newer operative procedures. If instead of showing new devices and new operations we should rather spend a little more time in telling the general practitioner, who is usually the first to see the patient, how to diagnose the condition, a real benefit

Fig. 1.—Right lower extremity illustrates position of limb in fracture of the neck of the femur.

would be conferred upon humanity by the orthopedist, because more cases would be diagnosed early enough for the various methods of conservative treatment to be effective.

Now, what are the pathognomonic signs in fractures of the neck of the femur?

A person who prior to a fall walked quite straight and without assistance, soon after a fall finds himself unable to get up without assistance. When the physician arrives he finds the patient in bed. The lower limb which is supposed to have sustained an injury is rotated outward, with the inner border of the foot pointing upward while the outer border of the foot resting on the mattress and pointing downward. When the patient is asked to lift the foot off the bed, he attempts to but finds it impossible. The first thing to think of in such a case is the presence of a fracture of the neck of the femur, provided, however, that palpation reveals no solution of continuity in the shaft of either the femur or lower down. Measurement from the anterior superior spinous process of the ilium to the internal malleolus of the same side, and the same measurement repeated on the other side, will give the indication as to the real shortening, if present. Usually one may find very little shortening in the early stage.

FRACTURES AT THE REGION OF THE VERTEBRÆ

Most of the physicians associate fractures in the region of the spinal column with severe symptomatic manifestations, such as, paralysis and disturbances of the nervous system, which in their minds is so frequent a consequence of the injury that it never occurs to them to think of such injury with seemingly slight symptoms and mild signs.

I have seen some cases with fractures of the bodies of the vertebræ with symptoms and signs so mild that only a thorough examination and proper x ray revealed the true condition.

Many cases of backache, if thoroughly gone into and properly x rayed, will reveal the presence of a fracture of the vertebræ or some part of its appendages as the starting cause, having been overlooked by the family physician, as well as by the consulting surgeon.

When a patient gives a history of a sudden onset of pain in the back, which persists in spite of rest for a few days, traced to either a sudden wrench or even a sudden turn or fall, and accompanied by a spasm of the muscles of a small area of the spine, with presence of local tenderness, the physician will never make a mistake in diagnosing the case as a tentative fracture. He may then investigate further, to either corroborate or eliminate the above diagnosis.

It is indeed humiliating to have treated a patient for months or years for lumbago, with massage, baking, electricity and what not, and then after the patient has become tired of the ineffectual results, the physician, as a last resort, suggests a consultant. The examination will then reveal the presence of a fracture, which should have been given a chance to unite instead of being interfered with.

The third and last fracture which I intend to deal with in this paper is one, which is quite fre-

Fig. 2.—Shows the test for the ability of the patient to lift the foot and limb off the table. This is a very valuable test.

quent and is the least recognized, namely, fractures of the os calcis.

Speed states that of his record of 10,702 cases, he found ninety-two instances of fracture of the os calcis, or 0.86 per cent. He also credits Brind with the following statistics:

	Fracture	*Calcaneus*	*Per cent*
Billroth	663	7	1.1
Tietze	17000	206	1.2
Drenke	1845	29	1.3
Lemmen	3554	65	1.8
Brind	3460	63	1.82

Speed divides them into four varieties: avulsion

fractures, isolated fractures of the sustentaculum tali, isolated fractures of the trochlear process (peroneal tubercle), and compression fracture of the whole bone.

The compression fracture composes at least ninety

Fig. 4.—E. R. In spite of extensive fracture of fifth and sixth cervical vertebral bodies, patient attends to her daily occupation, walks around without any hindrance, and seems to possess fairly good health.

per cent. of all calcanous fractures. They are more common in men than women. All the cases of compression fracture that I have seen were in men, and all of them were produced by practically the same cause, falling from a height and landing on the plantar surface of the feet. All of them have had the same pathognomonic signs, sudden appearance of a flat foot after the injury, with inability to adduct the foot, and tenderness along the middle part of the os calcis, and swelling of the ankle, as well as at the plantar surface of the foot posteriorly.

It is, therefore, worth while remembering that a sudden appearance of a flat foot in a patient after a fall from a height and landing on the feet, which is accompanied by swelling and tenderness, the first thought should be fracture of the os calsis. This possibility should be excluded before any other diagnosis is entertained (Fig. 6a).

EPIPHYSEAL INJURIES

Kirmison points out an interesting physiological fact with reference to the epiphyseal cartilages, i. e., "It is very important to note," says he, "that the different epiphyses do not all possess the same physiological value."

Of the two epiphyseal cartilages in a long bone, one always plays a much greater part than the other in the development of the length of the bone. This epiphysis is termed the fertile cartilage. The nature of these fertile cartilages varies in the superior and in the inferior extremity. In the upper extremity the fertile epiphyseal cartilages are the superior extremity of the humerus, and the inferior extremities of the ulna and the radius. In the lower limb, on the contrary, the epiphyseal cartilages of the lower end of the femur and the upper end of the tibia causes increase in the length of the limb.

One must bear in mind that epiphyseal injuries in regions where the epiphyseal cartilage is fertile, though the injury at the time may seem slight and insignificant, may have a farreaching effect in the future. This is on account of early ossification of the part and shortening of the limb through cessation of growth, if the injury happens to affect the cartilage of one bone region. If the injury has taken place in one bone of a two bone region, such as the forearm, the cessation of growth taking place in one bone while the other keeps on growing normally, the adjacent part depending upon the two bones for normal articulation will eventually suffer from deviation and incomplete alignment. The family of the patient should, therefore, be told of such possible outcome, in order to avoid possible blame and legal complications (Figs. 6 and 7).

OTHER CAUSES FOR SHORTENING AND LENGTHENING

Shortening of a limb following fractures may be caused by: Overriding of the fragments and union taking place in that position; destruction of part of the bone as a result of infection at the point of fracture, or as a result of operative interference in nonunion, necessitating the removal of eburnated

Fig. 5.—Mrs. P. Injured in automobile accident. The surgeon treating the case failed to recognize the complete fractures and separation of the fourth transverse processes of the upper four lumbar processes of the right side.

ends, so as to be able to approximate the freshened fragments.

There are other causes which must be thought of, and my experience with them convinced me that they are not rare, e. g., deformities produced by the alignment. A person has sustained a fracture in a straight leg, and when the surgeon sets the bones he puts them in an attitude of a slight inward bowing. After the fractured bones are properly united, the patient will have a shorter limb on the injured side, for no other reason but for the difference of the directions of the bones of the two legs (Fig. 8). If, on the other hand, the patient, prior to the sustained fracture has had an inward bowing of the two legs and while the surgeon was setting the fractured bones, he failed to take cognizance of that fact, and placed the fractured leg in straight position. After the union, the patient will be the unhappy possessor

Fig. 6.—M. R. Fracture of left os calcis with marked flat foot, treated for sprained ankle for two months. Right foot for comparison.

of a longer limb as a result of the injury, which will be to him a greater inconvenience than if it were somewhat shorter. Lengthening of the fractured limb may also be due to irritation of the growth cartilage as an indirect cause of the fall.

This may be of great legal importance, especially in children. I have recently been called to court to give testimony in a case where a boy of seven, as a result of a fracture of the left leg, had an inch lengthening of that limb. The surgeon who had charge of the case was at first of the opinion that the lengthening of the limb was due to an irritation of the growth cartilage, until a thorough study of both lower limbs by inspection, palpation and measurements, as well as by study of the x ray plates, showed me that before the accident the boy had internal bowing of both limbs due to early rickets, and that the lengthening of the left limb was brought about by the corrected attitude in which the fractured limb was placed and permitted to unite. It is needless to emphasize the necessity of studying and comparing both limbs for the presence of the slightest deviation from the normal. X ray should also be taken of both sides for comparison.

Many women have bow legs, and some have

Fig. 7.—Showing marked deviation of right foot and mishapen astragalus caused by traumatic epiphyseal disturbance of the fibia four years prior to the taking of the x ray. Left foot for comparison.

knockknees. Quite a number of women cannot fully extend their forearms under normal conditions.

In children shortening of a limb following a fracture, if not due to disturbances of the fertile cartilage, has the tendency to correct itself in time, especially in the lower extremity. This is due to the stimulus of walking on the growth cartilages of the shorter side to a greater extent. It is, therefore, to my mind, not a wise policy to replace the shortening by building up the shoe too soon.

RADIOGRAPHY

Inspection, palpation, measurement, at times auscultation, will help the surgeon make a diagnosis, and decide upon the mode of treatment. The x ray should always be taken after a complete examination and diagnosis has been made, and should be considered as an aid in diagnosis and not as the alpha and omega of diagnosis.

From a legal point of view, however, an x ray is indispensable, and any physician who treats a fracture case without an x ray to confirm his diagnosis, does so at his own risk, and will sooner or later have cause to regret it. In order that an x ray should be of real service in the diagnosis as well as in the determination of the mode of treatment, the following important points must be remembered:

1. The x ray must be taken by an expert.

2. The anteroposterior views as well as lateral views of the limb must be taken, in order to ascertain the amount and direction of displacement, if present.

3. The normal limb of the uninjured side must always be taken for comparison.

4. X rays are only shadows, and as such the angle at which the part is exposed to those rays will make a difference in the finding, especially in the spinal column.

5. Beware of artifacts which may resemble fractures.

6. In young people of the adolescent age one must be on the lookout for the growth cartilage and ossification centres, which may be taken for fractures (Fig. 9).

7. The readings and interpretation of the x ray negative should be done by the surgeon, aided by the radiologist, and not by the radiologist exclusively.

8. Plaster of Paris is permeable to the rays, and can therefore be applied to the fractured part soon after the injury, followed by the taking of the x ray as soon as the patient can be moved to a place where the x ray apparatus is available.

9. Stereoscopic views are to be preferred for the study of complete displacement or impactions.

In taking x rays of the spinal column one must remember the following facts: In the upper four cervical the anteroposterior view can only be taken with the patient's mouth open, and the rays directed through the oral region. In the cervical region a splendid lateral view can be obtained and should always be taken. In the lumbar region due to the natural lordosis the rays of the tube do not strike all the bodies of the vertebræ alike, and also the angle formed by the junction of the sacrum and last lumbar is another obstacle to the rays. Hence one must be careful in the reading of the x ray plates taken of that region.

As for the significance of the x ray, in the determination of end results, I fully agree with Speed, that:

"A röntgenogram taken to show end results or late in the course of a fracture has no value, except in those cases of failure of union to determine the amount of callus or to help decide on operation for malunion.

"The ultimate test of the fracture result is functional, and not anatomical. Anatomical reposition seldom occurs except in open operations, and not always then. If the patient secures a functional result without gross deformity, no röntgen examination is necessary, and slight displacements which are present in large majority of cases might be misinterpreted by unskilled observers, and lead to trouble. These displacements become effaced in the course of time when functional use readjusts the bone structure in accordance with Wolff's law."

TREATMENT OF FRACTURES

Prior to determining the mode of treatment to be instituted in any particular case, the following considerations must be taken into account:

Age, sex, occupation of the injured. Though proper alignment of the broken parts is the prerequisite in all ages, if sustained by either sex, and in people of all occupations, the method of approach differs in different ages as well as in different sexes.

The essential point to remember is the fact that in the treatment of fractures simple methods are preferable to cumbersome apparatus.

It may be a backward idea to some physicians who like to be up to date in their methods of treatment, but notwithstanding the recent lengthy articles appearing in the various medical publications, I have a weakness for the treatment of fractures with plaster of Paris immobilization. After all the results count and not the method.

If one is an adept at handling the plaster and can judge as to how to pad the limb prior to the application of the plaster bandages, the application of an immobilizing bandage soon after the injury will have the tendency to prevent swelling. If the reduction is found to be imperfect through the x ray, by splitting the plaster cast transversely and proper wedging, one can correct overriding of fragments, angular deformities, and faulty alignments. After the plaster bandages have been applied I seldom find it necessary to remove the cast in order to correct the alignment.

As for the fear of ankylosis of joints so immobil-

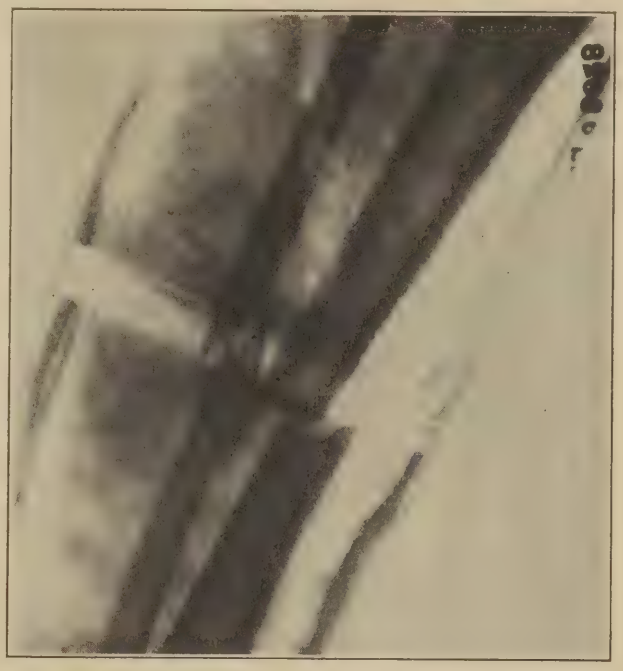

Fig. 10a.—J. H. Shows fracture of both bones of the left leg with marked displacement. The arrows show where the plaster boot has been cut through ready for wedging.

ized, except in those cases where the injury was so near a joint that it actually invaded the joint proper, I have never yet seen an ankylosis produced by the proper immobilization for a few weeks. On the contrary, I have seen poor results follow early mobilization of joints, abundance of callus formation due to early interference by too precipitate massage, baking, high frequency and ultraviolet, and other treatment.

Splints are good, if one knows how to adjust them. Plaster of Paris is excellent, if the physician knows how to apply it.

OPERATIVE INTERFERENCE IN FRACTURES

In passing I want to remark that if surgeons were more careful in their preoperative care of fractures there would be no need of operative interference in the large majority of cases.

I have seen many patients where their condition

was diagnosed as a permanent nonunion of fractured bone, and ordered to return to the hospital for operative interference. The condition improved under conservative and common sense methods without the need of the knife, and with the avoidance of mutilating corrections. Function stimulates the advent of blood to the affected region, with the invasion of a greater amount of calcium, resulting in callus formation and proper knitting of the bone fragments. Operative interference for correction of deviating deformities resulting from injuries to the epiphyseal cartilages deserves thorough and lengthy discussion.

As I stated, shortening of a limb in children may be temporary as the result of a slight overriding of the fragments, and usually corrects itself after a lapse of time by the stimulation of the growth cartilage in that region.

Hence operative interference in children and adolescents to correct such shortening is contraindicated. On the other hand, in shortening due to disturbance of the epiphyseal cartilage and involvement of the said cartilage, such shortening will increase as the years go by.

In discussing the psychological significance of injuries and diseases of lower extremities, in a previous communication, I have laid down certain rules by which I have been guided, and I believe that these rules deserve repetition.

1. Early and proper immobilization of the injured limb in order to eliminate the pain due to motion. Plaster of Paris bandages, properly applied, seem to serve the purpose best.

2. The encouragement of the patient to leave the bed as soon as practicable, and have him walk with the aid of crutches.

3. Removal of permanent support should be postponed until after the patient has been trained to walk without crutches, and has regained his selfconfidence. This prolonged immobilization has the effect of making the patient forget his previous incapacity and pain, and the regaining of his sense of security usually results in the ability of the patient to support himself on the injured limb without any difficulty, soon after the permanent removal of his immobilizing bandages.

4. In short, the necessity of bearing the old truism in mind that in dealing with ailments and injuries affecting human beings, we are dealing with beings in possession of emotions, impressions, and a nervous system in control of the impaired machine, and not, as a good many seem to think, a simple lifeless apparatus in need of repair.

There is, however, one class of cases in which immobilization of joints should be shunned, namely, in fractures sustained by patients subject to osteoarthritis of various joints.

SUMMARY

1. Fracture, though defined as a solution of continuity of bone, is most frequently accompanied by an injury to the soft tissues as well. The latter injury may at times be of even greater importance than the fracture of the bone itself.

2. In studying the symptoms and signs accompanying an injury which resemble a fracture, one must bear in mind that the symptoms being subjective depend a good deal upon the age, sex, social status and temperament of the injured, and hence need thorough scrutiny before reliance can be placed upon them. Even signs, though objective, may be misleading unless studied carefully and critically, before a diagnosis of fracture can be established, especially in obscure cases.

3. X rays should always be looked upon as corroborative and an aid in diagnosis, and not of exclusive diagnostic import.

4. In order that the x ray may be of real importance the interpretation should be done by both together, the surgeon in charge of the case, together with the radiologist.

5. One must become familiar with the appearance of the normal epiphyses at the various periods of adolescence in order to be able to determine whether or not any injury has taken place in that region. X raying the region of the uninjured side for comparison will certainly facilitate proper interpretation.

6. Not only in epiphyseal injuries but in fractures of the diaphyseal parts of bones, as well, is it essential that the injured side be x rayed as well as studied and observed for comparison, in order to detect the slightest deviation in form, shape or any other alteration which may have bearing upon the ultimate results.

7. The most important thing in fractures is restoration of function and if function is restored the x ray appearance, though disappointing, should be discounted for the best interest of the patient, and the physician as well.

8. Fractures of the neck of the femur, spinal column and os calcis, though of fairly frequent occurrence, are very often overlooked, resulting in permanent disability to the one so injured. It is, therefore, of paramount importance to bear symptoms and signs as well as the frequency of those injuries in mind, so that the physician is in a position to make an early diagnosis.

9. Epiphyseal injuries in children or adolescents, especially when the injury involves fertile cartilages, though seemingly slight and insignificant, may in years to come produce shortening of the limb as well as deviating deformities due to early ossification of the injured epiphysis. It is therefore essential that the family of the child so injured be informed of such possibility, and be asked to return the patient from time to time for observation.

10. Shortening of a limb in children caused by healing of a fracture of the long bones with a light overriding, provided the fertile cartilage is not disturbed will, if left to its own resources, in the majority of cases make up the shortening, especially in the lower extremity. The walking seems to stimulate the growth cartilage of the shorter limb to greater activity, and sooner or later both limbs will be of equal length. It is, therefore, a wise policy to encourage such stimulation by withholding the building up of the shoe on the shortened side for a while and watch the outcome.

The treatment of fractures and its outcome depend upon the man behind the method, and not upon any particular method of treatment, and any method which can restore function and give the patient the possibility to return to his usual occupation without delay, is the right method to be pursued.

Present Status of Treatment of Fibroid Tumors of the Uterus

JAMES N. WEST, M.D.
New York

In the treatment of fibroid tumors of the uterus we have to deal with a disease of quite frequent occurrence. Ellice McDonald in 175 miscellaneous autopsies held upon women, found that in those over twenty years old about one in every seven, or about fourteen per cent., had fibromyomata.

The fibromyoma, while essentially a benign tumor, possesses a strong latent power for harm. The weakening hemorrhages, the dangerous pressure effects, the tendency toward malignancy, the frequent occurrence during the childbearing period and its sterilizing effect, all unite in making its treatment one of the most important problems with which the physician has to deal in diseases of women. No definite rule can be formulated, since each case must be studied and treated according to the problems which it presents.

The histogenesis of fibromyoma is not fully understood. The latest investigation of the subject leads us to believe that the tumor is formed from the muscular coat of small arterioles. The true fibromyoma is a mesoblastic tumor and may undergo sarcomatous change, since sarcoma itself is a connective tissue growth and any carcinoma involving fibromyoma is necessarily heterogenic in its origin.

The adenofibromyomata have in their structure the epithelial cells of the glandular element and may undergo carcinomatous change without involvement from other sources. Either form of tumor may possibly become carcinomatous through metastasis from growths in other parts of the body. Myomatous tumors sometimes involve the whole uterus in a uniform hypertrophy of the myometrium.

The true fibromyoma possesses no histological unit but grows around a centre in interwoven fibres of nonstriated muscle and fibrous tissue, its density being determined by the excess of one or the other. As to why some tumors grow with greater rapidity and others more slowly we have no knowledge. As to the actual cause of their growth, we are still in the dark.

Until recent years the question of their treatment resolved itself into whether operation could be performed or not. If operation, whether total eradication by hysterectomy or removal of the tumors themselves by myomectomy, this depending largely upon the size of the tumor, the age and the general condition of the patient and the question of childbearing.

Recently another principle of treatment has come into use which adds an important resource beside operation, that is, the use of the x ray and radium.

For the purpose of treatment we may include three types under one heading, because we cannot usually make a differential diagnosis between these types of sufficient accuracy to segregate them, namely, fibromyomata, adenofibromyomata, and myomata of the uterus. With the most modern method of treatment with x ray and radium, sterilization, through their operation upon the ovaries, may be effected in one treatment. Through the action of these agents there is no doubt that most of the tumors will shrink and bleeding will cease.

The use of x ray and radium is not advised where inflammatory conditions in the pelvis exist or where there is a pedunculated fibroid or a submucous fibroid polypus. In the first instance there is a serious danger of causing fresh inflammation, and in the other instances there is danger of producing gangrene in the tumors.

The incidence of malignancy in these tumors at the time of operation has been placed by various authorities at from two to ten per cent. If we average this and say that in six per cent. of the cases malignancy exists we would reduce the treatment in those cases to that of malignancy of the uterus by the x ray and radium, and now the question of importance immediately presents itself, will the x ray or radium cure malignant disease of the uterus? If not, six per cent. of our cases may have their symptoms masked and reduction in the size of the tumor and an apparent cure only later on to die of malignant disease. It would therefore seem that if these tumors could be treated early when they were still small and checked or reduced in their growth that we would have an ideal method, without danger, in dealing with them, but in order to do this these patients would be sterilized through the treatment and many patients with fibromyoma may and do bear children. Therefore, it would not seem advisable from a sociological point of view to treat the cases at the earliest possible

moment with the gamma ray. It also often happens that we do not see or recognize these tumors until they have begun to cause serious symptoms.

Four patients whom I have seen consulted me on account of total inability to pass urine through pressure upon the urethra. Other patients whom I saw for the first time were in a cataclysmic condition through gangrene of the tumors. Such cases, of course, could only be relieved through immediate operation. On the other hand, in a considerable number of cases in which the patients were suffering from more or less severe symptoms, where systemic diseases, such as nephritis, diabetes, and tuberculosis, would make operation extremely dangerous, we would consider ourselves most fortunate to have an agent at hand which would enable us to give relief, in a large proportion of cases, without the danger of an operation.

The use of the x ray and radium in the treatment of these tumors will be considered in detail by Dr. William H. Meyer and Dr. George Stuart Willis in the two papers which follow.

As time for observation has become more extended, I find my views of treatment of fibroid tumors influenced by facts which time alone can demonstrate, namely, that the tendency toward malignancy is greater than I had thought in the earlier years of my practice. Second, that when myomectomy has been performed, the tendency for the formation of other tumors in this uterus is greater than I had expected it to be. This makes me feel that the radical field should be extended to a point beyond that which I formerly considered to be the proper one.

Assuming that the general health of the patient is good except for complications produced by the tumor, I would say that in women in whom childbearing has no important consideration and who are more than forty years of age, and having a fibroid which has begun to cause serious symptoms, a wise course of procedure would be to do a supravaginal hysterectomy, leaving one or both of the ovaries. All patients with pedunculated fibroids and submucous fibroids causing extensive hemorrhage should be operated upon. All patients with extensive tumors pressing upon important organs and causing serious functional disturbance should be operated upon. In pregnant women where the presence of a tumor seems a serious obstacle, fibromyomatous polypi, gangrenous fibroids, tumors of great size and rapid development, fibroid tumors associated with inflammatory disease of the tubes and ovaries, all tumors and fibroids in women past the menopause which have begun to bleed again, should be operated upon.

Now this leaves as suitable for treatment by the x ray and radium cases in which operative risks would be great on account of the systemic condition of the patient and cases of comparatively small tumors in women in whom the childbearing function has ceased to be a factor, and where the artificial induction of menopause is of no serious consequence.

The operation of myomectomy may be extensively applied in women of the childbearing age, where the childbearing function is of importance. It is, however, more dangerous than supravaginal hysterectomy. The mortality rate of the latter operation is less than one per cent. in the hands of many operators.

There are many methods of treatment which require little notice. The endocrine treatment of fibroid tumors is hardly worthy of mention. The methods of the present time which really offer relief are operation, radium and the x ray.

71 West Forty-ninth Street.

Radium Treatment of Fibroid Tumors of Uterus

GEORGE STUART WILLIS, M.D.

New York

The two main indications for radium in the treatment of fibroid tumors of the uterus are, first, small nonpedunculated fibroids in women approaching the menopause where hemorrhage is the chief complaint; second, when surgery is contraindicated because of some organic condition. The dose must be at least 1,200 milligram hours and we use a fifty milligram tube, screenage one and one half millimetre of silver, for twenty-four hours in the uterus. We also crossfire, using one hundred or two hundred milligrams of radium over the tumor mass. The skin area is divided into spaces about two inches square and each square is radiated for not more than one thousand milligram hours. The tube is placed routinely in these fibroid conditions one inch distance from the skin. This treatment may be repeated monthly until the tumor has disappeared. I present two case histories as follows:

Case I.—Mrs. B., married twenty-three years, no children. Menstruation had always been profuse. For the past two years she had been constantly spotting, with severe hemorrhages two or three times during the last year. Hemoglobin was 60, red cells 3,300,000. The patient had lost weight within the last six months. Except for a very high uric acid content her blood chemistry was normal. Urinary examination was negative. Upon examination, a fibroid about the size of an orange was felt posteriorly. The patient had seen a number of surgeons who suggested hysterectomy, but fearing an operation she was sent to me for radium treatment on June 3, 1922. At that time she received, externally, two thousand milligram hours, and one thousand milligram hours in the uterine cavity. On June 10th she received four hundred milligram hours intrauterine, and on September 30th, four hundred milligrams externally. On June 13, 1923, the tumor had apparently disappeared. She had never had any bleeding after the first month. Blood was normal and the woman was apparently well.

Case II.—J. W., aged fifty-two, was sent to me from the Harlem Hospital. Operation was refused because of an existing kidney lesion. Diagnosis was chronic interstitial nephritis. The tumor presenting completely filled the abdominal cavity crowding the liver upward, and it was impossible for the woman to walk. Pressure symptoms were such that the urine constantly dribbled and the woman was bedridden. The first treatment was given in June, 1920; one hundred milligrams of radium were introduced into the uterine cavity for twenty-four hours, externally four thousand milligram hours were given. The patient received about eight radium treatments after that.

The tumor diminished until it became about the size of a six months' pregnancy. After the second treatment the woman was able to work and had worked ever since. Her physical condition aside from the tumor mass was excellent.

116 East Fifty-third Street.

Röntgenotherapy in Myoma Uteri

WILLIAM H. MEYER, M.D.

New York

A summary of the cases of metrorrhagia, menorrhagia and fibromyoma uteri treated by x ray therapy at the Post-Graduate Hospital is here presented.

The series consists of forty cases treated during the past five years in which a sufficient time has elapsed to permit the drawing of justifiable conclusions. These forty cases can be divided into four groups depending upon the technic employed.

CLASSES OF CASES

1. In the first ten cases the old method of multiple area of crossfire through comparatively small portals of entry using from eight to sixteen areas at an eight inch focal distance with a supposed nine and one half inch gap and three and one half mm. of aluminum as a filter was employed. In these cases it was necessary to repeat the series at monthly intervals through the numerous portals of entry three or four times in succession before an amenorrhea was produced.

2. In the second series of ten cases the single factor altered was the thickness of aluminum filter which was practically doubled. By this method, still using multiple areas, crossfiring the number of series necessary to produce an amenorrhea was diminished. The majority were successful in one series.

3. No pronounced alteration in the method of treatment occurred until heavy filtration was employed, namely: In the third series of ten cases, the filter thickness was increased to the equivalent of about twelve mm. of aluminum. The focal distance doubled. In this series the portals of entry were materially increased in size and reduced in number, three to five large areas being the average; these administered on the same day if possible or all delivered in the minimum period of a week or ten days. (The voltage as measured by the spark-gap in all the foregoing remained practically the same.) In this series of cases we calculated to produce amenorrhea in one series and in this we were successful.

4. In the last series of cases the technic, which we are at present continuing, especially in heavy individuals, consists of using the same or larger portals of entry, with a further diminution in the number of areas, with increased filter thickness (employing three quarters mm. of copper) and an increase in the kilo voltage or penetration. By this method in the heaviest of cases we can practically guarantee the production of an amenorrhea in a single series. The number of portals of entry vary from one to four depending upon the heft of the patient and the size of the tumor.

In summarizing the results obtained in these cases, it is noted that there are no deaths and no untoward results of any kind ascribable to the use of the rays, though two cases are worthy of mention. In one, the only one of the series that came to operation, an apparently normal uterus was removed. (There were no adhesions.) Another in which a double mass was palpated, one proved to be a fibroid in which shrinkage later occurred. The other mass disappeared following an abortion of approximately three months, which was possibly due to the intense radiation.

The production of adhesive vaginitis, anemia, permanent gastrointestinal disturbances, adhesions and other changes ascribable to interference with the internal secretory functions of the ovary, are, as far as we are concerned, myths. In each instance the amenorrhea was complete and permanent. The minimal effect on tumor masses obtained was a shrinkage of at least fifty to seventy-five per cent. in size. In many instances previous palpable masses entirely disappeared.

Though we ourselves decide the need of further or continued treatment the clinical course of the cases is determined by the referring physician or checked in the department of gynecology.

Series	K.V. Peak	Focal dist. inches	Filter mm.	Area inches	Half Absorption in Al. mm.	Half Absorption in H_2O cm.	Amenorrhea No. area	Amenorrhea Series
1/	135+	8	3½ al.	2 to 3	5+	3½	8 to 16	2 to 3
2.	133+	8	6 al. or rotary	4 x 4	7+	5	6 to 12	1 to 2
3.	133+	16	13 al. or ½ cu.	6 x 6	12—	8—	3 to 6	1
4.	220—	16	¾ cu.	8 x 8	17+ Dose to skin, ¾ erythema	11+	1 to 4	1

The differences in effect of these four series of cases are best illustrated by the half absorption rate indicated in each.

Superiority of Radium Over Surgery in Cancer of the Uterus

WILLIAM H. KENNEDY, M.D.

Indianapolis, Ind.

It is a noteworthy fact that, although there exists much diversity of opinion on the many phases of the cancer question—chiefly in regard to its etiological and therapeutic aspects—there seems to be complete accord in the belief that this malignant disease is gradually increasing; likewise there is concurrence of opinion on the question of mortality. The fact that cancer is constantly exacting a greater toll of human lives may justly be regarded with deep concern, especially at a time when scientific research and the various modes of treatment for this condition are claiming so much of our attention. Although educational campaigns which have been and are constantly being carried on for the enlightenment of the laity may, to a certain extent, account for the apparent increase of malignancy—in so far as they lead to early diagnosis—coupled with actual strides in diagnostic methods, should not this greater incidence at least be counterbalanced by the application of therapeutic methods now at our command?

Unfortunately, there is no means of gathering and summarizing authentic data which would indicate the extent of the advances, if any, made in regard to cures, amelioration, or temporary relief effected, so that resort must be made to statistics in connection with mortality rates; and these must in turn be considered in proportion to the occurrence of the condition. It is, therefore, not with any measure of encouragement that the following facts are presented.

Confining our attention to the United States, we find, according to statistics compiled by the Bureau of Census, that there has been an increase in the incidence of cancer from sixty-three to the hundred thousand persons in the year 1900, to 76.2 in 1910, and, again, to eighty-six in 1921. Further, that the number of deaths in 1921 from cancer and other malignant tumors numbered 76,274, corresponding to a crude rate of eighty-six persons to the hundred thousand, against 83.4 in 1920, and 80.5 in the year 1919; and that the death rate for the year 1921 shows an increase of 36.5 per cent. over that of 1900.

That cancer of the uterus is responsible for the great majority of fatalities due to malignancy in the female genital organs is indicated by a compilation of statistics from the same source, for the year 1921: Of 11,181 deaths due to carcinoma of the female genital organs during 1921, 10,085 were attributed to uterine carcinoma—truly an appalling ratio!

In our own state of Indiana, these same reports show that death from all causes, in 1921, aggregated 35,220, of which 2,735 persons died from cancer, 426 cases of this malignancy being attributed to cancer of the female genital organs.

Inasmuch as educational publicity is furthering the cause of early diagnosis in regard to carcinoma, it will not, however, fully accomplish its purpose until women comprehend the necessity of an examination every six months, and until every physician is brought to a realization of the fact that examination of the female patient is not complete unless a thorough vaginal examination is made. When these conditions prevail, they will go a long way toward keeping a great percentage of patients out of the incurable class, by making feasible the institution of proper treatment during the incipient stage of the disease.

Although it is universally conceded that the earlier the diagnosis the more amenable is the malignancy to treatment, still the figures quoted above point to an increase in the mortality rate, notwithstanding the fact that a larger number of cases constantly are being diagnosed at an earlier stage in the process. In lieu of these facts, a realization of our shortcomings seems essential—the most plausible explanation of failure to prevent so tremendous a sacrifice of human lives appearing to me to be a hesitation on the part of some of our surgeons to relinquish an old therapeutic method in cases where a newer one has proved to be of greater value.

With the question of treatment in cases of uterine carcinoma we enter the province of the examining physician, for it is he who controls, in no small degree, the destiny of the patient. If habit is the guiding factor, the patient is most apt to be sent by him to a surgeon who, in turn, decides whether the case is operable or inoperable. If, however, the examiner is alive to more recent therapeutic achievements, the value of radium in the treatment of this condition will be uppermost in his mind; the surgical procedure will be reserved for cases in which radium is contraindicated. In view of these later developments, therefore, cases should no longer be designated as operable or inoperable, the terms curable and incurable having proved more fitting.

The value of radium in the treatment of cancer of the uterus first gained recognition through the excellent results attained in cases which were considered as not amenable to surgery. In many of these instances radium proved so effective that cures were attained where merely amelioration was anticipated. These were the socalled inoperable cases, which were relegated to the province of radium therapy as a last resort. Although we had hoped, in these instances, merely to be able to bring relief, we had obtained results achieved by no other method of therapy; and the relief thus afforded amply rewarded our efforts. Indeed, some of the cases which have been referred to us as incurable by competent surgeons are well today, and have been so for years. In this connection, Ewing, in a recent report of the Memorial Hospital, New York (1), states that "the unexpected success of radium treatment of cervical carcinoma seems attributable to two main factors: 1. The cervical tissues form a resistant filter so that relatively large doses of radium can be inserted in the canal and in the tumor tissues. 2. The majority of cervical carcinomas resemble the basal cell tumors and are more susceptible to radiation than squamous carcinoma. On the other hand, the inaccessibility of cervical carcinoma will always render it very difficult

to extirpate this organ without disseminating tumor cells. These facts will probably assert themselves sooner or later in the final decision as to the choice of treatment of cancer of the cervix."

One of the most encouraging indications of progress is the fact that radium is being used exclusively in cancer of the cervix by many of our ablest surgeons. It is of interest to note that Dr. Howard Kelly recently expressed the opinion that practically all cases of cancer of the uterus are inoperable—not in a technical sense, but inoperable, if the welfare of the patient is to be the first consideration. Moreover, in presenting these views on the efficacy of radium therapy in carcinoma of the cervix, he is but voicing the opinion of many of our ablest surgeons—among whom may be mentioned Crile and other surgeons at the Cleveland Clinic, Burnam, Ochsner, and many others—who are discarding surgery for a treatment of far greater value.

Concerning carcinoma of the fundus, on the other hand, most surgeons still favor the operative treatment, although, even in this connection, Kelly (2) has found that in cases where surgery was contraindicated, radium was employed not only with great success, but with prospects of prolonged and remarkable improvement. In some of these patients he found that curettage, at a later date, showed the changes characteristic of radium, and an apparent entire absence of any cancer.

Likewise, in borderline cases, in the hands of competent radiologists, results are far more encouraging than when surgical means are employed. In fact, it appears to the writer that this is one of the main fields in which radium has demonstrated its greatest value, unless it be in the treatment of recurrences of carcinoma of the uterus. Here, however, great discretion must be exercised, for if too far advanced or in too close proximity to the bladder or rectum, severe functional disorders may be engendered at the expense of their regression.

To those patients who, unfortunately, have been denied the privilege of an early diagnosis, hemorrhage is probably the most important of the symptoms concomitant to cancer of the uterus; in fact it is this condition which usually leads the patient to seek medical advice. Too often, however, the disease at this stage has invaded the contiguous tissue, and marked destruction, often accompanied by involvement of other organs, has taken place. Frequently there is an involvement of the rectum or bladder. To determine whether the latter has taken place, a cystoscopic examination must, of course, be instituted. If the examination discloses an involvement of the bladder, relief of the cardinal symptoms, for a short time, is all that can be accomplished.

The continuation, until rather recently, of surgery in the treatment of cancer of the uterus must not by any means be construed as significant of a great measure of success; it was employed, rather, as the best available means at hand, in the hope that a more efficient therapy would be evolved, by means of which mortality could be more greatly reduced. This, we believe, is attained through radium therapy.

According to records obtained from several of our large clinics, we find that only forty per cent. of cases of cancer of the uterus which come for treatment are operable. Of this forty per cent. there is a mortality rate of ten per cent., leaving thirty-six cases out of one hundred that survive operation. According to their own statistics, a claim of twenty-five per cent. well, after five years, means that twenty-five per cent. of thirty-six cases (which is nine) remain well. Thus, the claim of twenty-five per cent. is misleading, as it does not mean twenty-five cases out of a hundred, but in reality only nine.

These figures and similar records cannot fail to strengthen the prevailing opinion as to the inefficiency of surgery in combating this condition. It therefore seems incomprehensible that there are still some surgeons who cling to the older methods in the treatment of cancer of the cervix; and we hope, in the near future, that this fallacy of vision will give way to better judgment. It is appalling, when given the final analysis, that we should still continue with a treatment that has so little to offer.

The knowledge gained by years of experience with radium has brought about a comprehension of its great therapeutic value; also a familiarity with its limitations. Judgment of radium therapy should be based on present day accomplishment exclusively, not on results obtained in our early work. Technic then was crude in comparison with that of today, it having since constantly undergone improvement. Ten years' experience with this form of radiotherapy in uterine cancer has afforded us sufficient opportunity to evaluate results thus far derived, in the light of which we feel no hesitation in predicting even proportionately greater strides in the near future, in the treatment of this disease.

Even the most enthusiastic radiologist, however, will not fail to acknowledge that there are limitations beyond which he should hesitate to venture, the decision in each case being influenced by many factors, among which may be included the extent, type, location of the metastasis, complications, radiosensibility of the patient, and, to a great extent, by his own particular experience with radium therapy. Unless great discretion is exercised much suffering will result, and radium will become as discredited as is surgery for the relief of this condition. For, while the practice of radium therapy—although still a comparatively recent one—has undoubtedly proved to be the method of choice in the treatment of malignancy by cautious and scientific workers, its practice in the hands of those who are inexperienced is greatly to be condemned.

In conclusion, it is earnestly to be hoped that a closer cooperation will develop between the surgeon and the radiologist, for it is not the writer's intention to claim that radium therapy is a cureall for malignant conditions. Although he believes that its efficacy is infinitely greater in curing and relieving the special condition under discussion, often a combination of radium and surgery gives better results than either means employed exclusively. Only through constant and serious application and scientific research by examining physician, surgeon, and radiologist, can the best results be attained.

A Plea for the Preservation of the Perineum and a Modified Prophylactic Episiotomy for the Prevention of Perineal Lacerations*

D. DEUTSCHMAN, M.D.
New York

Perineal lacerations during parturition are as old as the human race and the most frequent of all labor complications. Their occurrence is in direct proportion to the attempts, on the part of the obstetrician in charge, to facilitate and hasten the course of labor, by the premature application of modern mechanical and technical methods. These perineal injuries are frequently unavoidable, regardless of the experience of the operator and the dexterity and skill employed. According to figures given by Olshausen, Ballandin, Schroeder, Williams and many other obstetrical authorities, these perineal lacerations occur in from twenty-two per cent. to sixty-six per cent. in primaparæ and in from ten per cent. to fifteen per cent. in multiparæ.

The factors predisposing to intrapartum perineal lacerations are numerous, the most common of which are the following: Disproportion between the presenting parts and the vulval outlet; abnormality in the mechanism of labor, such as improper flexion or extension of the presenting parts; sudden and rapid expulsion of the fetus, especially when followed by the administration of pituitrin; a narrow pubic arch; rigid perineum, as the case may be in senile primaparæ; mechanical interference, etc. No part in the field of obstetrical and gynecological activities has been so little respected as the perineum during parturition. The injury of the perineum during childbirth often forms the primary focus of infection of a widespread pelvic pathology with all its concomitant results, frequently terminating in mutilating, major, pelvic operations, which result in subsequent sterility and many other permanent deformities.

Numerous therapeutic and mechanical appliances have been introduced in the field of obstetrics for the purpose of relieving the agony of childbirth and accomplishing a rapid and successful delivery of the child. Little, however, has been offered for the purpose of preventing traumatic complications of the pelvic muscles during parturition. A vast number of ingenious methods have been devised for the purpose of repairing perineal lacerations, but few methods have been described for the prevention of their occurrence. Those that have been advanced have proved ineffective and, therefore, are rarely employed by the profession. Giffard, a prominent English obstetrician, of the eighteenth century, was the first to call to the attention of the medical profession the advisability of attempting to prevent perineal lacerations during childbirth. Since then, a few methods have been advanced for the preservation of the perineum.

In all these methods, attempts are made to support the perineum, by pressing upon it during the height of perineal distention, caused by the pressure of the presenting parts, in the course of the uterine contractions. These socalled perineal pressure methods, for obviating perineal injuries, are uniformly highly unsatisfactory, as they do not accomplish the purpose for which they were devised. By repeatedly subjecting the perineum to pressure by the presenting parts from within and the hand of the obstetrician from without, during the process of perineal distention caused by the uterine contractions in the second stage of labor, these muscles are traumatized by this maneuvre. At the same time the normal blood supply to these muscles is obstructed and subsequently deprived from performing their normal biological function of muscular elasticity and contractility and ultimately retarding, instead of accelerating, the normal course of labor.

Another method practised by some obstetricians for the preservation of the perineum during parturition is the socalled fetal head pressure method; i. e., instead of supporting the perineum directly, in order to control the degree of perineal tension, it has been suggested to support the head of the fetus by pressing against it, during the uterine contractions, thereby directing the course of the head in the vulval cavity and correcting, at the same time, it is maintained, overflexion or overextension. This latter method, to my mind, is not better than the former and furthermore, it is more dangerous than the perineal pressure method mentioned above. Subjecting the fetal head to the pressure of the obstetrician's hand may result in intracranial hemorrhage of the newborn and, at the same time, it does not prevent perineal lacerations. It is not the presenting head alone that tears the perineal muscles, but the shoulders or any other part of the baby. Any mechanical manipulation employed in delivery may cause the same damages to the perineum.

Another method used for the prevention of perineal lacerations, during the second stage of labor, is the episiotomy, one which is comparatively little used, owing, apparently, to the unsatisfactory results obtained from its employment. The modification of this method, to my mind, would make an ideal procedure to prevent the mutilation of the pelvic floor during parturition. The indication for the performance of an episiotomy, as outlined by the limited number of obstetrical writers, should be modified. According to these obstetrical authorities, this little, simple and highly valuable operative procedure should only be used in emergency cases, as a last resort. In other words, it is advised to perform an episiotomy only after the perineum has been stretched to the point of maximum elasticity, resulting from repeatedly prolonged and continuous pressure upon it by the presenting parts and when the rupture of the perineal muscles seems imminent. Only under such conditions is it advised to perform an episiotomy, by making an oblique incision on

*Read before the Clinical Society of the Bronx Hospital, October 8, 1923, and before the Obstetrical and Gynecological Society of the Bronx, January, 1924.

FIG. 1.—Cutaneous scarification outlining points and course of sutures.

either side, between the anus and the ischial tuberosities, and thus relieving the tension of the perineum by directing the pressure of the presenting parts to the path of least resistance, i. e., in the direction of these incisions. It is the modification of this little operative procedure and the extension of its indications that I wish here to advocate.

FIG. 2.—Introduction of sutures without making incision.

MODIFICATIONS OF EPISIOTOMY

Based upon the highly satisfactory results obtained from a number of obstetrical cases, I take the liberty of recommending the following modifications in the performance of an episiotomy, as a reliable method for the prevention of mutilation of the perineal muscles and, necessarily, for obviating rectoceles and cystoceles, which are so frequently observed, following normal deliveries without any visible tears of the perineum:

Episiotomy should be performed for prophylactic purposes and not as an emergency requirement. It should be a method of choice and not one of necessity. The incision should be under control and not allowed to be torn by the pressure of the presenting parts or by any mechanical interference. Sutures should be introduced before the incision is made and the landmarks should be definitely and clearly preserved. There should be a unilateral and not a bilateral incision. The point and the course of the incision should be changed.

I wish to discuss briefly and separately each of these points.

EPISIOTOMY AS A PROPHYLACTIC MEASURE

Episiotomy should be performed as a prophylactic measure for the preservation of the pelvic muscles, especially when difficulty during the second stage of labor is expected, such as a rigid perineum, version, the application of forceps or the contemplated use of any mechanical assistance. Under such conditions a prophylactic episiotomy should be a prime indication, thus creating more room to permit the free introduction of the obstetrician's hand into the uterine cavity, without any fear of subjecting the perineum to the risk of being torn, as a result of manipulation. The perineal muscles should not be subjected to prolonged and forcible pressure by the presenting parts, in the course of the repeated stretching of the pelvic floor. When the presenting parts have reached the perineum the danger of stretching the levator ani muscles begins. Whether this forcible stretching will terminate in permanent injury to these muscles, cannot be predicted before termination of labor.

Subjecting the perineum to a prolonged and forcible stretching, as the case happens during the second stage of labor, may often result in a concealed laceration of the levator ani muscles or paralysis of these muscles, which is just as bad, if not worse, than a complete tear of the perineum. Solution of continuity frequently results in lacerations of the vaginal wall, sphincter and levator ani muscles, without external signs. The effects of these lacerations are observed only a few weeks postpartum, by the gradual appearance of a marked rectocele or rectocystele. This is usually discovered by another physician, to whom the patient applies for an opinion on her postpartum morbidity and who is surprised to learn that she had been torn during her last confinement, in spite of the fact that her confinement doctor had honestly assured her that she had passed through her difficult labor without even a scratch. These pelvic damages, whether of a visible or concealed character, are the unavoidable results from subjecting the perineum to prolonged pressure distention exerted by the presenting parts and the manipulation in delivering a large passenger through a small passage.

FIG. 3.—Incision following course of levator muscle.

Therefore, to obviate these predominating intrapartum pelvic injuries, more room should be created in the vulval outlet, by performing a prophylactic episiotomy, in cases of obstruction at this outlet, such as rigid perineum, large head, abnormal presentation, mechanical interference, etc. The episiotomy should be performed as soon as the presenting parts begin to stretch the perineum and not delayed until these muscles have been stretched beyond the point of muscular contractility and biological regeneration, at which time an episiotomy will be of no more benefit to the perineum, as the damage to the perineal muscles will have been completed. An early prophylactic episiotomy saves the perineum from being mutilated by the presenting parts in the process of the second stage of labor; it prevents rectocystoceles, by saving the vaginal portion of the levator muscles; shortens the perineal stage and hastens thereby the process of labor.

CONTROL OF INCISION

The control of the incision for the prophylactic episiotomy and the preservation of its landmarks are of prime importance. The introduction of the sutures should be done before making the incision and this should be carried out as follows: As soon as the presenting parts have reached the perineal floor and bulging has begun, introduce three long, loose sutures, using a large curved needle with the proper suture material, introducing the needle through all the layers between the skin and the anterior vaginal wall, i. e., the skin, subcutaneous tissue, adipose tissue, bulbo cavernosus, fibres of the levator muscle and through the anterior vaginal wall. These sutures should be introduced about one third of an inch apart, beginning from the edge of the vulva and placing them in a semi circular course, with the convexity upward, outward and downward, so as to follow the direction of the fibres of the vaginal portion of the levator muscle.

The sutures should be left loose in the vaginal cavity, lest they tear during the perineal distention, caused by the pressure of the presenting parts, and for the same reason the ends of these sutures should hang loosely outside, without attaching any clamps to them.

As soon as the perineum has undergone a reasonable degree of stretching an incision should be made between the first and the second sutures and, if this incision does not create sufficient room to allow the presenting parts to pass through, as will be manifested by the degree of the perineal tension, it should be prolonged in the direction of the next two sutures, thus preventing this incision from being torn during the height of uterine contractions. After the baby has been delivered and, while waiting for the expulsion of the placenta, the prophylactic sutures are pulled together and tied, without the slightest damage to the perineal muscles, producing a clean wound with perfect coaptation of the edges and the landmarks clearly and definitely preserved.

Prior to the introduction of the sutures it is advisable to make a semicircular cutaneous scarification, outlining the direction of the sutures and the course of the incision.

INTRODUCTION OF SUTURES BEFORE INCISION IS MADE

In selecting the point and the course of the incision for the prophylactic episiotomy, one should be careful and guard against damaging the levator muscles too much, as these are the most important muscles of the entire female pelvic cavity. Their proper function and exact dynamic value have as yet not been fully estimated, according to the opinion of numerous modern gynecologists. By their multitudinous attachments and the distribution of their fibres, these muscles have the power of balance and hold in equilibrium all the organs of the female pelvic cavity. While it is impossible to make any incision in the female rectovaginal field without encountering some of the fibres of the levator muscles, I venture to state that the oblique incision, i. e., the one made between the anus and the ischial tuberosities, as practised by the limited number of obstetricians who make use of an episiotomy, is the one that causes the most damage to the levators, by striking the shanks of these muscles. It also cuts the fibres of the levators across. Again, the posterior longitudinal episiotomy, i. e., where the incision is made in the rectovaginal septum, is equally unsatisfactory, because it does not heal well, owing to the connective tissue of which it is made up. Besides there is the danger of tearing through the anal sphincter, which may be caused by a sudden expulsion of the fetus, during a strong uterine contraction.

In order to avoid the ill effects that may result from either a posterior longitudinal or anterior oblique incision, I make a round incision. I begin at the edge of the vulval orifice, at a point about one half inch above the fusion of the labiæ majoræ and minoræ, coursing upward, outward and downward, between the previously introduced prophylactic sutures and following the course of the fibres of the vaginal portion of the levator muscle I strike neither the shanks nor cut across this muscle, thus causing the least injury to the levator muscle and, consequently, preventing rectocystoceles, so commonly observed shortly after parturition.

UNILATERAL INCISION

There should be a unilateral and not a bilateral incision. The cut should be made on the side which undergoes the greater amount of pressure caused by the presenting parts and, prolonging this incision, if necessary, in the direction of the sutures, will create ample room for the delivery of the baby, without subjecting the vulva to a double scar and, at the same time not damaging the perineum.

RECAPITULATION AND CONCLUSION

1. Perineal lacerations during labor are frequently unavoidable.
2. Prevention of these lacerations by supporting either the perineum or the head of the fetus is unsuccessful in the majority of cases.
3. The episiotomy, when used as a matter of emergency requirement, is ineffective because the muscles have been traumatized too much to undergo regeneration.
4. A prophylactic episiotomy, without introducing the proper sutures, before making the incision, will destroy the landmarks and will not give the desired results.

5. The anterior oblique or posterior longitudinal incisions are ineffective and frequently dangerous.

6. The modified prophylactic episiotomy as described in this paper is more effective. It protects the perineum and prevents rectocystoceles. This modified prophylactic episiotomy has given me such gratifying results, when the patients have been examined several weeks postpartum, that I take the liberty in recommending it to the profession and trust that the results obtained will be equally satisfactory.

Importance of Early Diagnosis in Ectopic Gestation

GILBERT FRANKLIN DOUGLAS, M.D.
Birmingham, Ala.

In opening a discussion on this subject from the viewpoint of the title given we realize that to touch all phases would be impossible in the short time allotted, so necessarily I shall mention only some of the more salient points. The number of cases for each individual physician are so few that it is hard to get an idea of statistics unless we quote from those compiled by others; a number in this paper are from Schumann.

About the middle of the eleventh century Albucasis, an Arabian physician, called attention to the condition and reported the first recorded case. Many different definitions are given for this condition but for brevity we may summarize by saying that it is the condition where the ovum lodges and imbeds in any situation outside of the uterine cavity. The frequency of this condition is much greater than is generally thought. The statistics of all the hospitals of Philadelphia for the year 1918 showed one ectopic gestation to every 167 full term intrauterine pregnancies.

The age at which this is most frequent, according to Farrar's reports, showed sixty-three per cent. of the women were between twenty-four and thirty-three years of age; of course this is the most active childbearing period of a woman's life.

There are many varieties, as lodgment of the ovum may take place anywhere in its passage from the ovary to the uterine cavity.

A few varieties (quoting from Kelly) are:

Primary Forms	*Secondary Forms*
Interstitial	Intrauterine
	Abdominal
	Intraligamentary
Tubal	Abortion
	Tuboabdominal
	Tuboovarian
	Abdominal
	Intraligamentary
Ovarian	Abdominal

According to statistics probably the most frequent sites of lodgment in the tube is the ampulla portion, and the isthmian portion the next.

The causes are many; usually we are unable to determine the cause for the particular patient in mind. These may be divided into the following:

1. Obstruction, from without the tubal lining.
2. Obstruction from within the tubal lining.
3. Anomalies of the tubal lumen, accessory tubes, etc.
4. Decidual reaction in the tubes.
5. Growth of the fertilized ovum being so rapid outside of the tube until when it enters it can't pass.

These are being further divided: 1. a, Peritubal adhesions, perisalpingitis and other conditions; b, constriction from pressure of tumors and other causes. 2. a, Salpingitis destroying the epithelial coat; b, malformations were found in fifty-four per cent of sixty-eight cases reported by one author; c, the cause widely accepted being the simple one of some mechanical arrest of the fecundated ovum during its tubal journey brought about by inflammation.

SOME OF THE TERMINATIONS OF ECTOPIC PREGNANCY

1. Early death of ovum with complete resorption and restoration of the tube to its normal state.
2. Death of the embryo with formation of tubal mole.
3. Tubal abortion.
4. Rupture of the pregnant tube into the peritoneal cavity.
5. Growth and development to term, until fetus dies or is delivered by section.

A FEW OF THE SECONDARY TERMINATIONS OF ECTOPIC PREGNANCY

1. Tuboabdominal pregnancy.
2. Secondary abdominal pregnancy.
3. Tuboovarian pregnancy.
4. Intraligamentous pregnancy.

END RESULTS OF ECTOPIC GESTATION

1. Resorption of products of gestation.
2. Tubal mole.
3. Hematocele which may be: a, diffuse; b, solitary; c, may become infected.
4. When fetal development continues the fetus may become: a, lithopedion; b, mummified; c, adipocere; d, skeletonized; e, may suppurate.

A study of the anatomy and pathology of extrauterine pregnancy shows that an ovum can develop only on a spot free from epithelium, sinking through decidua to rest on subepithelial layer. Necessarily

*Read before the Chattahoochie Valley Medical Association, Warm Springs, Georgia, July 8, 1924.

there must be some abrasion or disease along the tract making possible a nidus for the ovum's resting place.

Further statistics show that the bleeding occurring at the time of a ruptured ectopic gestation is from the endometrium of the uterine cavity, venous in type, rather than from the tube affected. The uterine bleeding literally is of sympathetic nature—sympathetic labor—at the time of rupture of the ectopic pregnancy.

The size of the decidual cast depends on the duration of pregnancy. According to statistics a large percentage of the fetuses in ectopic pregnancy are deformed or show malformation. Von Winckel thinks that fifty per cent. show deformity. As a rule the fetus dies before the third month.

Many cases of recurrences of ectopic pregnancies are reported where the affected tube, or a part of it, has been left in place at the time of operation for ruptured ectopic pregnancy. There are so many that I do not believe it wise to leave the tube intact, as the factor causing the first ectopic pregnancy may cause a second to occur in the same tube. As to the advisability of removing the other tube, I do not think it fair to remove it merely as a preventive measure; we should have some definite reason.

The question of diagnosis is the important part of this subject, as possibly there are many more cases not diagnosed before rupture than there are diagnosed, and if it were possible to make a correct diagnosis before rupture in all of these cases we would have fewer fatalities charged against us.

So long as life and growth go along we have no hemorrhage. Pain is one of the first symptoms. Practically every case shows some menstrual anomaly if such be recognized.

CONCOMITANT SIGNS OF PREGNANCY

1. Amenorrhea.
2. Morning sickness.
3. Pain and tingling in breast.
4. Increased pigmentation of areas, nipples, etc.
5. Softening of cervix.
6. Enlargement of uterus.
7. Cyanosis of vaginal mucosa.
8. Increased antiflexion of uterus.
9. Frequency of urination.
10. Abderhalden reaction; this latter is accepted as of little diagnostic value.

Long intervals between pregnancies is an alleged cause of ectopic gestation. We all appreciate that preexisting pelvic diseases are important etiological factors. On bimanual examination the uterus is usually found in antiflexed position. The enlargement of the uterus is not in proportion to the duration of pregnancy. Microscopic findings of chorionic villi in decidual tissue establishes the diagnosis of intrauterine pregnancy. Decidual cells without villi predicates the existence of extrauterine pregnancy. Bimanual examinations, where ectopic pregnancy may exist, should be made with extreme gentleness lest the tube be ruptured.

As a rule there is low temperature, 99° to 102° F.; leucocytosis of low degree ten to twelve thousand. Blood pressure is usually unchanged before rupture.

Ectopic gestation should at once be suspected when a woman, who has menstruated normally for a long period, suddenly goes over from four to twenty days, notices blood coming from vagina differing in quality, color, and quantity from the normal, which continues, and who has pains generally severe in one or the other side of the pelvis or in the hypogastric region.

In the asthenic type we at once notice depression as a dominant factor. The history as a rule is as follows: While doing her work the woman was seized with agonizing pain in the lower abdomen followed by syncope, skin cold, clammy, leaky and anemic. The temperature was below normal. There was collapse and shock, pulse rapid and thready, rapid shallow respiration, sighing for breath, contracted pupils, facies of extreme anxiety, restlessness, thirst, air hunger; mentally not impaired, but too sharply acute.

With these symptoms, and the physical finding of tenderness and other conditions, it is suggestive of ectopic pregnancy, but we have some differential points of diagnosis to keep in mind, as follows: Intrauterine pregnancy with threatened abortion; hemorrhage from tube or ovary not related to pregnancy; acute salpingitis; acute appendicitis; ovarian cyst with twisted pedicle; rupture of gastric or duodenal ulcer; ureteral or renal colic.

If there is blood in the cul de sac the patient has pain on defecation or on rectal examination.

Where there is intrauterine abortion, bleeding is more profuse and red in color. Where hemorrhage is from a ruptured ectopic pregnancy, blood is more scanty and brownish in color, it is the venous type. The temperature as a rule is higher in ruptured ectopic pregnancy than it is in intrauterine abortion. Ectopic pain is usually localized over one or the other tubes, begins suddenly with greater severity, with general abdominal pain later. The mass is felt more to one side.

In uterine abortion no mass is felt on either side, and the uterus is larger than in ectopic pregnancy. Positive histological diagnosis is only to be made by finding chorionic villi cells in suspected tissue.

After mentioning a few points as to frequency, age, anatomical and pathological conditions, symptoms and diagnosis, I feel that we all certainly appreciate the magnitude of this subject and the responsibility that every one who makes diagnoses and treats women have in making as early a diagnosis as possible. This responsibility does not rest on those of us who are doing gynecology and obstetrics as a specialty alone, but on every one whether he be doing general surgery, internal medicine, or any of the other specialties or general practice, if he is treating women he has his share of the responsibility, for the diagnosis has to be made at some time and the earlier the better.

Now as to treatment, after diagnosis has been made, I feel this can be summed up almost in one word, operative, of course there are a few cases in which it might be better to wait a little, but after supportive treatment has been administered as a rule the quicker we get in and ligate the bleeding vessels the better chance will our patients have for recovery.

Toxemia of Pregnancy Complicating Hydatiform Mole*

IRVING SMILEY, M.D.
New York

Of necessity, it is impossible to take up any of the problems connected with this interesting phase of pathological pregnancy in the short space of time allotted me. Nevertheless, a few words touching upon the salient features of this condition before proceeding to the history of the case will not be amiss.

Hydatiform mole is a vesicular degeneration of the chorion and is evidence of epithelial proliferation resulting from lack of a protective ferment or secretion in the body. It is usually an end result which takes months to develop. Clinically, moles are divided into two classes—those in which the mole is expelled in toto, and those in which it is adherent from invasion of the uterine muscle.

While the etiology and pathology of these neoplasms are not yet fully understood, they are assumed to be based on biological reactions. The process by which the placental tissue undergoes degeneration and becomes gradually detached from the uterus, and the causes which produce these changes, are not well known. It is, however, certain that the influence of the ovary plays an important part, particularly the graafian follicle rather than the corpus luteum. Despite the fact that corpus luteum cysts are present in nearly all cases of mole of either microscopic or macroscopic size, no relationship between the coexistence of mole and corpus luteum cyst can be shown. The luteum cyst regresses on removal of the mole. It is not the cause of the mole, but the reverse, as is shown by the reversion of the cyst. The influence of the mole is that of stimulation of the lutein tissue. A general hyperplasia of all the lutein material of the ovary takes place in normal pregnancy, and when there is hypertrophy of the villi, as takes place in the mole, the intensified process so stimulates the normal lutein hypertrophy that cysts develop. It would seem that just as the corpus luteum of ordinary pregnancy has a defensive function as regards the toxines of pregnancy, the presence of these cysts might be construed as an attempt on the part of the organism to multiply the luteum cells when they have to neutralize the greater quantity of toxins which are generated by moles. This seems to be the most logical explanation of the processes involved, although not definitely proven.

The characteristic clinical picture of mole is the occurrence of bleeding in the early months of pregnancy and a uterus which is disproportionately large for the supposed state of pregnancy. The bleeding usually begins about the second or third month, is more or less continuous, and may at times be profuse. The mole may occur at any stage and at any period of pregnancy, but is more frequent in the early months. Many of the cases present light toxic manifestations.

That the condition is not devoid of danger is shown by a mortality of from ten to fifteen per cent. The causes of death are hemorrhage, sepsis, uterine perforation with subsequent peritonitis. The relationship between moles and chorioepithelioma is too well known to be dwelt upon here.

The tendency at present to remove the uterus in all cases where mole is diagnosed should be condemned and combatted in the strongest possible manner. Manual removal of the mole is the method of choice, with vaginal hysterotomy resorted to if necessary. Any suspicion of malignancy should call for total hysterectomy.

To sum up briefly I may state the following: Moles originate from placental tissue and their formation is influenced by changes in the ovary. Most likely these changes take place in the graafian follicle. Moles cause cysts of the corpus luteum. They should be treated from the viewpoint of hemorrhage and sepsis, bearing in mind the possibility of chorioepithelioma. Manual removal is the method of choice, and if found impossible vaginal hysterotomy. Any suspicion of malignancy should call for hysterectomy.

The following case is of interest because of the presence of a hydatid mole without any fetal elements, together with what appears to be a true toxemia. Toxemia associated with pregnancy is not uncommon, but that combined with a pathological pregnancy makes the case instructive and interesting.

CASE.—The patient was admitted to the hospital on June 7, 1923, with the following history obtained through the kindness of her family physician. Mrs. F. S., aged twenty, married, with one child ten months old. Her family history was negative. She began to menstruate at the age of thirteen, was always regular, of the thirty day type, four days' duration without pain. Ten months previously she had given birth following a normal delivery. Her last period was in the first week of November, 1922, four months after the birth of her child. Soon after skipping her period she began to vomit; this lasted for two weeks. In April, or the fifth month, the vomiting began again and became very severe, so much so that she was forced to go to bed. She said that she felt fetal movement. In May she began to spot intermittently. Under the influence of lutein injections there was slight improvement for two weeks, when the entire symptom complex returned. Vomiting became more severe and spotting again took place. She was unable to retain anything. The urine at this time showed marked traces of albumin, pus and hyaline casts. The blood pressure was 135 over 60. About this time a slight irritating cough developed with bloody expectoration. Such was her history when she was admitted to the hospital.

Examination revealed the following: The patient looked acutely ill, emaciated (had lost twenty pounds in weight), temperature a little above 99°,

*Read before the Bronx County Medical Society, May, 1924.

pulse 110, respirations 20. Heart and lungs were negative. Abdomen: fundus uteri was very sensitive to touch reaching to one inch above the umbilicus. Vaginal examination: slight bloody discharge was oozing from the vagina, cervix was soft admitting the tip of one finger. Eyes: fundus showed a venous congestion. Blood examination: 3,720,000 red blood cells, 7,800 leucocytes; 72 per cent. polymorphonuclears; 28 per cent. small lymphocytes. Blood chemistry urea nitrogen 18.9 mgs., creatinin 1.5, sugar 0.7. Daily examination of the urine showed diminished output, marked traces of albumin, hyaline and granular casts and many red blood cells.

In spite of all treatment the vomiting continued. Blood pressure went to 142 and the output of urine diminished to eight ounces in twenty-four hours. The cough was irritating and the mucus was constantly streaked with blood. The pulse ranged between 110 and 125. The patient seemed to be going down hill and after the consultation with the medical department it was decided to terminate the pregnancy. On June 12th the cervix was dilated sufficiently to allow the insertion of bag. Within twelve hours the patient went into labor, pains became quite severe and on the following day the bag was removed. On inserting the hand into the uterus a great mass of hydatid tissue was removed piecemeal. After making sure that the uterus was empty it was packed and the patient was returned to bed.

During convalescence the temperature dropped to normal but the pulse remained 110. The pathologist reported no signs of malignancy. X ray picture of the chest proved negative. She was discharged from the hospital on June 23rd. On August 11th she had her first period lasting five to six days, had put on weight and felt normal.

The prominent features of the case were as follows: 1. Although the diagnosis of mole was not made in this case, the objective findings presented a true clinical picture of a hydatid mole. 2. The total absence of any fetal parts. 3. The extreme loss of weight, the severe and persistent vomiting in spite of all treatment, the elevated blood pressure, and the renal involvement as manifested by the laboratory report justifies the diagnosis of a true toxemia of pregnancy rather than the mere toxic symptoms often associated with moles. 4. In view of the pulmonary symptoms, the negative physical signs and negative x ray findings, it is plausible to assume that the pulmonary condition may have been due to metastases from the uterus, which, upon removal of the mole, cleared up.

I am indebted to Dr. Max Rosenthal, chief of our department, for permission to report this case.

1018 East 163d Street.

Spontaneous Rupture of the Uterus

LEOPOLD GOLDSTEIN, M.D.,
Camden, N. J.

I wish to report a case of spontaneous rupture of the uterus, which occurred in the maternity section of the University Hospital in the service of Dr. Barton Cooke Hirst, professor of obstetrics at the University of Pennsylvania, with a brief discussion of the frequency, and causes of this rather rare condition.

C. H. Davis (1) has made a careful review of the literature and reported several cases of ruptured uterus. He divides the causes of this condition into five groups, namely, uterine, fetal, pelvic, vaginal and intrauterine complications. Lobenstine (12) states that generally contracted pelvis of moderate grade is the condition most often responsible for uterine rupture. He tabulates 588 contracted pelves in 1,342 uterine ruptures, or 40.83 per cent. In the statistics of the Lying-in-Hospital of New York, there are twenty-one contracted pelves in forty-six cases of complete rupture, or 45.65 per cent. In his series of 417 cases of uterine rupture, Trask considered that it was spontaneous in sixty-seven cases. Placenta previa is a cause of rupture of the uterus. Lobenstine (12) had five cases from this cause in forty-six complete ruptures, and thirteen in twenty-nine incomplete. Schmauch says that in placenta previa there are six times as many cervical tears after version as there are following spontaneous delivery. In my case, a diagnosis of premature separation of a normally situated placenta had been made. Louis E. Phaneuf was unable to find any reference to cases of spontaneous rupture which had been associated with premature separation of the placenta. He reports two cases in which spontaneous rupture was associated with premature separation.

Rupture of the uterus is more common in prolonged labors than in short ones. Trask gives a list of 147 cases in which the time from the beginning of labor till the rupture occurred is recorded. Thirty-eight ruptures occurred within the first six hours; thirty-six during the second six hours, and 104, or seventy per cent., in the first twenty-four hours. Collin's statistics of 15,850 normal cases, show that in 13,412 cases, or eighty per cent., the labor was terminated within six hours. In Lusk's series the cause was attributed to the use of ergot in sixteen cases. The fetal causes of rupture are mainly hydrocephalus, malpositions, and malpresentations. Among uterine causes are retraction ring; cicatrices following Cæsarean section, previous ruptures or trauma; tumors of the uterus, anomalies of the uterus, such as uterus duplex and uterus unicornis. The chief pelvic cause is contracted or deformed pelves. Among the intrauterine complications, instrumental delivery, version, and manual removal of the placenta are the chief causes of rupture.

The cause of spontaneous rupture is not known. The examination of a spontaneously ruptured uterus may show no disease in the uterus. The muscle

may be entirely normal. Numerous theories have been advanced as an explanation for its occurrence. Lobenstine reports twenty cases in his series of forty-six cases. Ivanhoff studied the uterus histologically in nineteen cases. He was unable to explain the rupture on the basis of histology, although he found considerable variation in the percentage of elastic and connective tissue. The theory of defective hypertrophy of the wall in the fundus is supported by the fact the seat of rupture almost always occurs in the fundus. Sänger states that while some of the theories advanced are acceptable in many cases, a satisfactory explanation of the etiology in all cases has not been advanced thus far. Examination of spontaneous rupture in cases where Cæsarean section had been performed previously, usually show the rupture to have taken place in the old scars. Bauereisen has found telangiectic changes in the lower uterine segment, and he believes that careful micropathological studies will find this a more frequent condition than inflammation, sclerosis, and fatty changes. Bauereisen also noticed a scarcity of elastic and connective tissue in the vicinity of the rupture. DeLee says, spontaneous rupture is excessively rare; it is found that trauma almost always preceded it.

Spontaneous rupture is much more frequent in multiparæ than in primiparæ. Uterine weakness because of previous pregnancies may be a decided factor in the occurrence. In my case there had been seven pregnancies. Ruptured uterus from various causes is more common in multiparæ than in primiparæ; Brandl gives the proportion as eight to one. Trask reports thirty-one primiparæ in 417 cases; Jolly, thirty-seven in 455 cases; Merz, fourteen in 320 cases; Petren, four in fifty-four Swedish cases; Cristenan, four in seventy-seven cases; 482 ruptures gathered from Brandl, Winckel, Koblanck, Kolaczek, *et al,* show 432 multiparæ, against fifty-seven primiparæ. Any operation upon the uterus that leaves a scar or fixes the organ, renders it vulnerable to rupture should pregnancy occur. Trask (1856) collected four cases of rupture following Cæsarean section. In 1886, Krukenberg reported twenty cases of rupture following Cæsarean section, and states that in fifty per cent. of all pregnancies after the old Cæsarean the uterus ruptured. Breitstein (13) reports a case, and Harrar (14) reports four cases of rupture following Cæsarean section. As previously stated, Davis reported four cases of ruptured uteri. In his fourth case, the rupture followed five deliveries and was apparently spontaneous. One of his cases followed application of forceps and attempts at the performance of version. The second case occurred in a patient who had had a previous Cæsarean section, and the third followed forceps operation.

REPORT OF AUTHOR'S CASE

Case I.—Mrs. M. S., aged thirty-two, married fifteen years, was admitted to the University Hospital on October 7, 1921. She had seven children, the oldest fourteen years old and the youngest four years old. Date of last period was January 25, 1921; confinement was expected on November 2, 1921. Her past medical history was negative. She had had four miscarriages; three were spontaneous, and one was selfinduced, two and one half years ago. Her menses commenced at the age of thirteen years, came at twenty-eight day intervals, and lasted five days. Her previous pregnancies had always been normal. Her condition during this pregnancy was good. She had no epigastric pain, no headache, no edema, no constipation. She had some varices of the vulva and thigh. Pelvic measurements: iliac spines 25 cm.; iliac crests 30 cm.; trochanters 32 cm.; external conjugate 22.5 cm.; internal conjugate (diagonal) 12 cm.; true conjugate 11.25 cm.; right oblique 25 cm.; tuber ischii 11 cm.; posterior sagittal 9.5 cm.; circumference of abdomen, 102 cm.

The history of her illness on October 7, 1921, was as follows: On October 6th she took a seidlitz powder. The following morning at 9 a.m., while at stool she was suddenly seized with stabbing pain in the abdomen. Since then, she had had severe constant, abdominal pain resembling labor pains, but apparently worse in the lower abdomen. She had not fainted. She had no cough, but was short of breath and was thirsty. She stated that she felt fetal movements shortly after the beginning of the pains. The patient appeared pale and looked quite ill. Pupils were dilated and reacted to light. The heart rate was rapid, but no murmurs were heard, and there was arrhythmia. The lungs were negative. The abdomen was globular and swollen to the size of an eight and one half months' pregnancy. The fundus reached about midway between the umbilicus and the sternum. The abdomen was tense and tender throughout. The uterus was tense and tender. No other masses were palpable. It was impossible to palpate the position of the child. There was apparently no rigidity of the anterior abdominal muscles. By auscultation, the fetal heart sounds were heard to the left and below the umbilicus.

Vaginal examination showed that the cervix was dilated about one finger; membranes not ruptured; cranium presenting; head not engaged; slight rectocele and cystocele present, perineum relaxed.

On October 7th a blood examination was made, showing red blood corpuscles, 4,000,000; white blood corpuscles, 22,000; hemoglobin, 78 per cent. Blood pressure was 95, 65. At 6 p.m. the patient vomited ten ounces of dark coffee colored fluid. At 8 p.m. she complained of more pain, and the abdomen was more tense than on admission. At 8.30 p. m. red blood corpuscles were 3,700,000, white blood corpuscles 21,000, and hemoglobin 74 per cent. At 9.00 p. m., a vaginal examination showed the same findings as on the first examination.

At 10 p. m., after about ten hours of observation, the patient showed no tendency to improve nor had she become much worse. The entire staff (Dr. B. C. Hirst, Dr. E. B. Piper, Dr. Kornblum) had seen her, and the unanimous diagnosis of "premature separation of a normally situated placenta" was made. In view of the apparent desperate condition of the patient, immediate operation was advised by Dr. B. C. Hirst.

At 11.30 p. m., operation was performed by Dr. F. V. Janvier and Dr. E. B. Piper. The vagina was disinfected with iodine and packed with gauze. Upon opening the peritoneal cavity through the usual incision for Cæsarean section, a considerable quantity of dark blood escaped. A dark, blue, spongy mass of tissue presented in the abdominal opening, which

proved to be placenta bulging through a rupture in the fundus of the uterus. The infant was immediately extracted but was in rigor mortis at the time of delivery. The placenta came away with the child. Two ampoules of ergot and one of pituitrin were given immediately. The ruptured uterus contracted, and there was little free bleeding. A high amputation of the uterus along with a bilateral salpingooophorectomy was performed. There was an ovarian cyst on the right side about the size of an orange. The cyst was removed and proved to be a dermoid cyst. The cervical stump and broad ligaments were peritonealized in the usual manner. Massive and numerous blood clots were removed from the peritoneal cavity. The abdominal incision was closed. The condition of the patient was fairly good throughout the entire operation, but because of the large amount of blood lost, five hundred c. c. of salt solution was given intravenously.

On the following day the patient's condition was very good and she was quite comfortable. On October 10th, a blood examination showed white blood corpuscles, 24,000, hemoglobin 43 per cent. On October 27th red blood corpuscles were 3,200,000; white blood corpuscles, 12,000; hemoglobin, 60 per cent. The patient was discharged in good condition on October 30th.

The interesting point in this case is that the symptoms were of such a character that a correct diagnosis could not be made. S. D. Van Meter (6) reports a case of spontaneous rupture resembling mine, in that the symptoms completely masked the true condition. Williams states, "In a number of cases, the hemorrhage following the accident was so slight as not to give rise to symptoms, and the condition escaped recognition until operative procedure became necessary for the removal of the fetus." In my case, the hemorrhage was very slight, and the condition was not discovered until operation. In such cases, where the correct diagnosis is in doubt, it is well for the patient to be in a hospital where operation can be performed at a moment's notice.

B. C. Hirst asserts that the accident is more frequent now than formerly, and this is usually an evidence of error in diagnosis or faulty technic. He also emphasizes the fact that the diagnosis is not so easy as one might suppose, and this is particularly the case in spontaneous rupture of the fundus. Finally, Hirst states that the routine abdominal section is not a necessary treatment in every case of uterine rupture. He says, "The hasty application of inappropriate means to extract the uterine contents or a clumsy effort to employ the right methods," increases the number of cases. He also adds, "that this accident is rightly regarded as a reproach to the physician in whose hands it occurs."

Hirst reports that of six cases occurring in nine months, every one resulted from instrumental or manual interference, and makes the statement that "undoubtedly, unskillful use of instruments, manual procedures, and failure to recognize dystocia are responsible for most ruptures." Of these six cases, in one, an effort to evacuate the uterus with curette forceps at the third month, for what was thought to be eclampsia but was probably hysteria, resulted in a perforation of the uterine wall, and the extraction and detachment of twenty feet of the woman's small intestines.

In another case, a woman was brought to the University Maternity by two physicians. One of them said he suspected that the uterus was ruptured, as in his last examination he believed he felt the liver. It was found that the uterus was not only almost completely torn away from the cervix, but both arms of the full term, overgrown infant had been pulled off, and two feet of the woman's intestines, stripped from mesentery, were hanging out the vulva. In a third case, the diagnosis was not made until operation. In a patient coming to the Howard Hospital a month after delivery, with what Hirst thought was an intraperitoneal abscess in the region of the umbilicus, at operation an abscess was found caused by a rupture in the fundus uteri from tube to tube. This rupture had never been suspected.

Louis E. Phaneuf, of Boston, reported two cases of spontaneous rupture associated with abruptio placentæ. As mentioned previously, he could not find reports of any cases of this condition.

Case II.—Mrs. M. P., primapara, aged thirty-three, married ten months, expected to be confined about April 15, 1918. On March 3rd, after being jolted in a street car, she commenced to bleed. She showed signs of exsanguination when examined. Her pulse was rapid, thready, and of very poor quality. She was blanched and in extreme shock. The uterus was firm, tense, painful to palpation, and the size of a large, full term pregnancy. There was no dilatation of the cervix, labor pains were absent, and fetal heart sounds were not heard. Because of the marked hemorrhage and the lack of dilatation of the cervix, it was decided to perform a laparotomy. On operation the uterus was found ruptured in the median line half way between cervix and fundus. The rent was through the peritoneum and muscularis, but not through the endometrium. A small stillborn fetus was delivered. Half of the placenta was separated, which was quickly removed, together with the membranes. The uterus was sutured in two layers. The patient died.

In this case, hemorrhage was the prominent symptom. In my case, hemorrhage was very slight and the patient's condition was unchanged for several hours.

Case III.—Mrs. A. K., married eleven months; confinement expected about April 25, 1919. She was admitted to St. Elizabeth's Hospital on April 27th; she was bleeding slightly; her pulse was 90 and of good quality. An hour later the pulse was 120, thready, and of poor quality. The uterus was tense and tonic. An immediate abdominal delivery was decided upon on account of the hemorrhage and the long rigid cervix without dilatation. On opening the peritoneal cavity, a rent about two inches long, running obliquely from the fundus toward the right tube, was incised in the median line. The placenta was practically separated. A small stillborn fetus at term was extracted by the breech; the placenta, membranes, and clots were removed, and the cervix was dilated from above. The uterine incision was sutured in two layers with No. 2 chromic catgut. The patient made a good ether recovery. She was given eight hundred c.c. of saline solution under the breasts, as well as a shock enema. She made a good recovery

and on May 23rd was discharged, the twenty-sixth day after operation.

S. C. Van Meter, of Denver, reported a case of spontaneous rupture of the uterus. In his case, a diagnosis of placenta previa was made by two physicians who had examined the patient. The patient, aged thirty-two, was eight months' pregnant. While walking in one of the parks, she suffered severe abdominal pain which she concluded was the commencement of labor. She was able to walk to a street car and reach the maternity home. Here the diagnosis of placenta previa was made. She had a normal temperature and pulse. The os was slightly dilated, and owing to her flesh and abdominal rigidity, the position of the fetus was not determined. Being unable to make a diagnosis, Dr. Van Meter was inclined to accept that of placenta previa. After watching the patient that afternoon and night, during which time there was no evidence of shock, and no progress towards delivery, the necessity of emptying the uterus became evident. The patient was prepared for operation. The hand was inserted into the uterus, the foot grasped, and the body delivered in the usual manner; but in attempting to extract the aftercoming head, the neck was suddenly severed. The fetus was macerated. On further examination the vagina was found to be filled with omentum, which cleared up the diagnosis.

The abdomen was opened in the midline. In the fundus of the uterus was found a transverse rent from horn to horn. The omentum was adherent to the posterior lip of the tear. The remaining exposed surface of the rent, except about three fourths of an inch in the right angle, was old and not bleeding. The omentum was freed from its adhesion to the uterus and the rent closed up. The patient made an uneventful recovery.

This case is of interest because the diagnosis of placenta previa was made, and the real condition not discovered till late. In my case, a diagnosis of premature separation of placenta was made.

In cases where the diagnosis is doubtful, operation should be performed early so as not to endanger the life of the patient. This case also resembles mine in that the chief symptom was pain. Hemorrhage was not a symptom in either case.

F. S. Oastler (9) reported two cases in 1918.

Case IV.—The patient, twenty-five years of age, single, was admitted to Lincoln Hospital on November 10, 1917, Para II. She gave a history of a previous pregnancy that was terminated by a basiotripsy following exhaustion and death of the fetus. The patient was admitted to the hospital at 7 a. m., having had pains for six hours. Strong contractions continued through the day and at 5 p. m. a sudden cessation of pains occurred. The contour of the abdomen changed, and a large mass could be palpated under the ribs on the left side, with a smaller mass low down on the right side of the abdomen. The patient rapidly went into collapse. On operation, the child was found free in the peritoneal cavity. The uterus was found to be contracted, and showed a transverse rent at the level of the uterovesical fold. A supravaginal hysterectomy was done and the patient made a complete recovery.

J. W. Long (4) reports a case of spontaneous rupture occurring during labor. Case: Mrs. A., aged thirty-two, married thirteen years, no former pregnancy, she was taken in labor at term on March 25, 1913, at 3 p. m. By 10.30 the head had descended well into the pelvis. At the height of a uterine contraction, the patient suddenly cried out complaining of undue pain in the abdomen; she had slightly hurried breathing for a few seconds, but there was little change in pulse. On examination, the head which was presenting had receded. Within five minutes after recession of the fetus the placenta was expelled spontaneously. The abdominal pains ceased, and the patient complained only of tenderness on palpation. The diagnosis was then made of ruptured uterus. Uterine examination was made and a large rupture in the left side of the uterus was discovered. An abdominal operation was performed. A longitudinal rupture was found through the left side of the uterus coming from deep in the cervix up through the body to Bandl's ring. The uterus was removed. The patient recovered.

Ross McPherson (5) reported a case of spontaneous rupture of the uterus.

Case V.—K. T., aged thirty-three, para II., was admitted to the New York Lying-in-Hospital, with the following history. She was pregnant in 1912 for the first time and was delivered by a high forceps at term, the child living only a day and a half. At the time of admission, she considered herself five months pregnant. The day before admission, she was seized with sudden, sharp, abdominal pain and felt somewhat faint. No history of accident or fall was obtained. She was admitted on the next day in a critical condition. When seen she was in extreme shock, pulseless, and with all the signs of abdominal bleeding. A saline infusion and the usual shock treatment were given, which failed to have any beneficial effect. Under ether anesthesia, the abdomen was opened, and the cavity was found filled with blood. A five months' fetus was found in the cavity and attached by the umbilical cord to the placenta which was still in the uterus. The uterus was ruptured transversely across the fundus. The fetus and placenta were extracted, and a rapid supravaginal hysterectomy performed. The patient was given a transfusion following operation, at the close of which she was conscious, pink cheeked, and with pulse at wrist of good quality. The convalescense was unmarked by complications.

Dr. John H. Telfair (7) reports a case of spontaneous rupture in which no manipulation had been made. His patient upon admission to Fordham Hospital at 10.30 p. m. on February 28, 1916, was in a condition of profound shock, presenting evidence of internal hemorrhage. She had no pains, and showed a moderate amount of bleeding from the vagina. Examination under ether showed a breech presentation. Operation was performed. The laceration of the uterus consisted of a transverse rupture of the vaginal vault anteriorly, extending to the left, opening up the broad ligament, and extending upward to the junction of the upper and lower uterine segments. A craniotomy and extraction was done, followed by an immediate hysterectomy. The patient died on the table.

Gordon Ley, of London, reports a case of spontaneous rupture of the uterus.

Case VI.—His patient, a multiparous woman,

aged forty-six, was admitted on February 10, 1917, to City of London Lying-in-Hospital. This present pregnancy was her twelfth. She had had nine full term labors, one instrumental, the last being in 1913, and two miscarriages, the last in 1914. She was at full term. The pregnancy had been normal to the thirty-fifth week, when she had a considerable hemorrhage lasting for one day. Since that date, she had slight losses until February 9th, when she had another considerable loss. There had been no pains. On February 10th, she was anemic; temperature 97; pulse rate 80; left occipitoanterior position. Fetal heart sounds were heard. There were no pains until February 11th when after a labor of one and one-quarter hours the baby was born alive. Ten minutes after completion of the third stage, the patient complained of sudden dyspnea. She became restless and her breathing was difficult and labored. The anemia increased, the pulse became feeble and rapid, and she died in fifteen to twenty minutes. A tentative diagnosis of pulmonary embolism was made.

On performing a postmortem examination, the following condition was revealed. There was extensive retroperitoneal hemorrhage into the substance of the left broad ligament, which originated from a rent in the left wall of the lower uterine segment. On opening the uterus longitudinally along its right border the placental site was seen on the posterior wall of the lower segment. The microscopical sections showed an apparently normal puerperal uterus lined by a decidua.

In this case, rupture was associated with placenta previa. Ley has seen three other cases of spontaneous rupture, all of which occurred in a Cæsarean section scar. He states that it might possibly be considered that erosion by villi would weaken the wall of the uterus in the region of the placental site, and therefore tend toward the occurrence of rupture. But in all sections of placental sites that he examined, a thin layer of decidua had separated the villi from muscle. He thinks, therefore, that we must assume that the causative factor does not lie here.

E. M. Colie (3) reports a case of spontaneous rupture of the uterus. He states that Dr. Brown and Dr. George L. Brodhead have also reported cases.

Colie's case was in an Irishwoman, thirty-four years of age, who had had six previous labors, all easy. She came under observation a month before her time of confinement. The first stage of labor lasted ten to twelve hours. After dilatation had taken place, there was no further advance. The membranes were unruptured. The patient complained of pains other than the labor pains. The student who was on the case went out for lunch, thinking that with unruptured membranes and regular pains, he was safe in so doing. He stayed out for one hour and on coming back he found the patient in bad condition. He made a diagnosis of internal hemorrhage. Dr. Colie was called in to see her, and made a diagnosis of ruptured uterus. Dr. Colie, considering that laparotomy offered nothing in this case, did a rapid version and extraction. The rent was felt in left uterine horn. The patient died in five minutes. No cause for the rupture could be found. There was no obstruction, the head was not large, and it was fairly flexed but not well engaged.

The two cases reported by George L. Brodhead occurred in multiparæ with normal pelves. Both had short labors, and both with a previous history of very easy labors. One of the patients died before the postgraduate intern could reach her. The other case was diagnosed immediately, and the patient operated on; the uterus was sewed up and the woman made a good recovery.

As regards treatment, abdominal section is required in the majority of cases. B. C. Hirst emphasizes the fact, however, that many a case of ruptured uterus may be saved by gauze packing of the pelvic and of the uterine cavity. The pelvic packing is left in for four days, when it is removed and replaced by fresh gauze. The packing is removed in twenty-four hours from the uterus. Packing is the indicated treatment in those cases where the rupture is in the lower uterine segment, cervix and vaginal vault. If the rupture is anterior or lateral, if there is much intraperitoneal hemorrhage, or if either the placenta or the fetus has escaped into the abdominal cavity, an abdominal section is required, and most likely a hysterectomy. In cases of much blood loss and shock, blood transfusion or the intravenous use of normal saline is of the greatest benefit to tide the patient over the critical period. Where there is much blood in the peritoneal cavity, and where there is need for haste, the Hirst method of performing supravaginal hysterectomy will save time. In his method clamps are placed on all arteries to check hemorrhage, and the uterus then removed. The clamps are removed one by one as the arteries are tied.

Petren in analyzing 754 cases of ruptured uterus found that of 501 cases treated conservatively there were 361 deaths, or a mortality of seventy-two per cent., while in 174 cases operated in there were ninety-two deaths, or a mortality of fifty-three per cent; of the 347 uncomplicated cases reviewed by Klein, 149 were operated in with a mortality of forty-four per cent; 198 were treated conservatively with a mortality of fifty-two per cent.

CONCLUSIONS.

1. Rupture of the uterus can occur without apparent cause. There are usually severe symptoms, such as pain or hemorrhage that should call the obstetrician's attention to the possibility of ruptured uterus. In other cases, several hours may elapse before symptoms are sufficiently marked to cause alarm.

2. It may be impossible to make a diagnosis of spontaneously ruptured uterus. On the appearance of symptoms pointing to internal hemorrhage, or other grave condition, laparotomy should be performed.

3. In all doubtful cases, the patient should be sent to a maternity hospital where she may be kept under observation, and radical treatment instituted when occasion arises.

4. No matter how badly off the patient may seem to be, prompt surgical measures may save her life.

5. Packing of pelvic and uterine cavities in ruptures of lower uterine segment may save the patient.

6. The value of actual blood transfusion is inestimable.

7. A careful examination of the patient should be made whenever she complains of abdominal pain.

The Senile Heart

LOUIS FAUGERES BISHOP, M.D., Sc.D., F.A.C.P.,
New York

In the days preceding the advent of modern cardiology a book was written by Balfour, a great clinician, entitled *The Senile Heart.* This book was spoken of twenty-five years ago as a model of clinical study and observation and was, undoubtedly, delightful reading, and illuminating. Since then there has been great advance and with the advantages of the new knowledge of the heart that has come through the studies of laboratory workers and of clinicians with the electrocardiograph, it seems the time has come when someone should approach the subject again.

The whole idea of senility has changed throughout the world. Old age no longer protrudes itself as a definite fact. The people of the present generation do not retire at a certain age; either men or women. So we are compelled, more than in former times, to fix a definite age for our senility. This age is probably not as early as it was formerly, for people do not begin life as early as they did. In this country education is much more prolonged and the easier circumstances of modern life make it possible for children to stay away from work longer. Nevertheless, the senile heart is a definite fact.

The most striking symptom of the senile heart is distress in the chest when a person attempts to do something which in former years he could do without much effort and one of the things that we must do in treating such a person is to teach him to respect this distress in the region of the heart and not to push beyond that point.

To no one as much as to the heart specialist does age appear purely relative. A man is as old as the flesh of his heart. We find middleaged people with infantile hearts and very young children with hearts, for all the world, like men of ninety.

A man of eighty-five comes to me who has a blood pressure of 120 and from time to time I see a child whose blood pressure is over 200. So the senile heart is not a matter of years but of condition. It may develop at any time. It does not surprise me any more when a man of thirty-five or forty shows, by technical examination, to have all the characteristics of a man twice that age. The senile heart is not a heart with a definite disease, but a heart which has undergone deterioration in the same fashion as appears naturally in extreme old age.

Fig. 1.—The senile heart.

If you are able to pass a life insurance examination or if you are otherwise informed that your heart is healthy and yet you cannot exert yourself as you formerly could without distress in the front of your chest, you are developing a senile heart and it behooves you to turn the hands of the clock backward by a suitable diet and a suitable regimen. If you do not, your days will become uncomfortable ones, with a great loss of efficiency. To turn the hands of the clock of the senile heart backwards it is necessary to do those things as a duty, after thirty, that you loved to

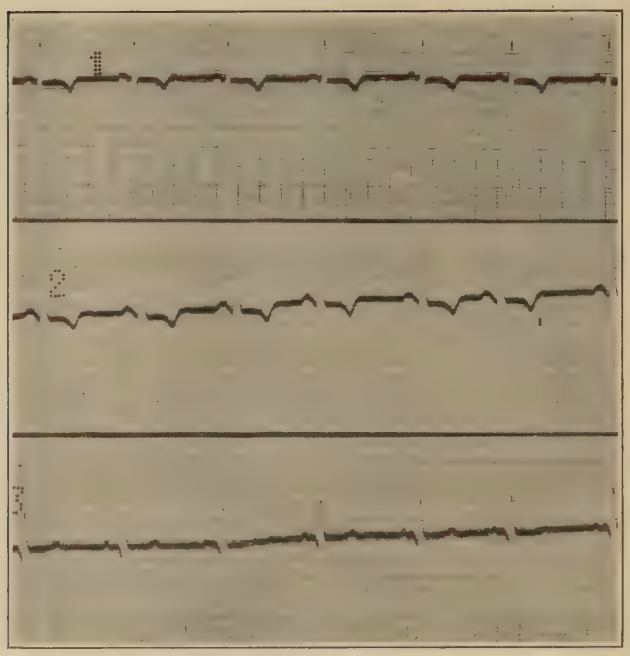

Fig. 2.—Electrocardiogram of the senile heart, showing weak left ventricle. The T wave is directed downward in leads I and II.

do before twenty. You must learn to rest and play, to live on simple food, to stifle undue ambition, and to cultivate pleasant emotions and a sound philosophy.

CONTRIBUTING CAUSES

In addition you must attend to all your focal infections, however trivial they may seem; that dead tooth with the gold cap on it and pus around its roots must be sacrificed. Those innocent tonsils must be guillotined, or at least go to the electric chair. The socalled catarrhal condition, wherever it is situated, must be treated. The skin can no longer be allowed to be a leathery covering, like the cover of an old book, but must be made into an active functional membrane, like the skin of a healthy child. The colon must be depopulated of offending germs and a new community of healthy organisms established.

If the heart is merely senile before its time, or only tired and poisoned, these things will be enough, but if permanent damage has been done and after this reformation of life and cleansing of the body has taken place there are still pains in the region of the heart on exertion, or shortness of breath without exertion, the ship which bears your health is in shallow water and you must take aboard a pilot.

Do not go to a physician when you are forty or sixty years of age to be cured of a senile heart, but go to him to have your senile heart taken care of and

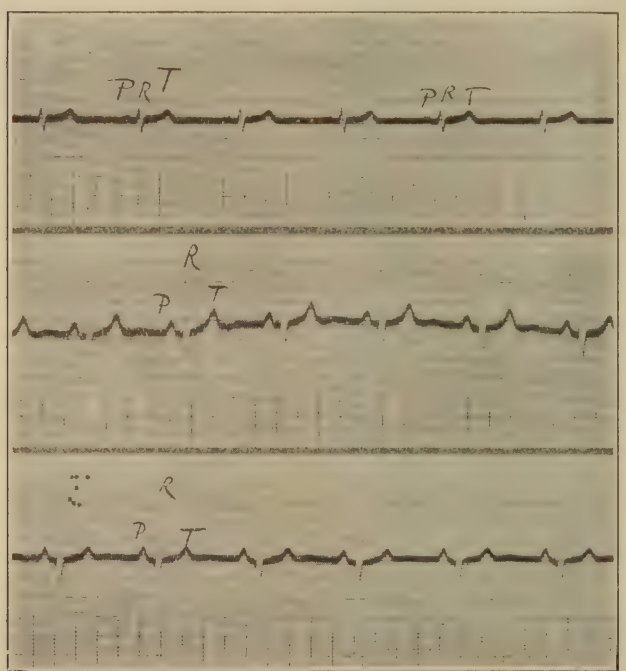

Fig. 3.—Electrocardiogram of infantile heart, showing sinus arrhythmia and relative right predominance.

Fig. 4.—The infantile heart.

to be inspected and guided at regular intervals. In this way only can you attain added years of life and comfort. You cannot get it without such help.

FREQUENT EXAMINATION

The physician who is interested in this art of helping people with senile hearts will make a complete technical examination with charts and records and will direct you to come back once a year to have new charts made and compared with the year before. If your heart is in need of a certain type of lubricant in the shape of a simple remedy, he will teach you how to take it continuously and not in the larger amounts that is urgently needed if your heart is allowed to get into serious trouble. Heart symptoms, such as severe pain becoming habitual, should be avoided, because one attack breeds another.

Not only do we encounter the too mature heart but we encounter, many times, the immature heart.

A large number of people suffer from a condition which was named during the war as neurocirculatory asthenia. This is a long name and it is used to cover a multitude of things that are not just alike. Nevertheless, it is a good name, because it is a name which recalls to the experienced physician a group of people with a particular kind of trouble. Many of these people have hearts, which either have never attained maturity, or which have relapsed together with their whole circulations into the immature type. People with this trouble have all the instability of children, with the cares and worries of age. The pulse shows a youthful irregularity of the sinus type. Their blood pressure is low as in children. Their hearts show a right sided predominance, instead of the dominant left ventricle that should be found in robust maturity.

This form of heart trouble is in contrast to the senile heart. These people may truly be said to be old people with infantile hearts.

If old age could be prescribed like a drug it would be a useful remedy to the person with neurocirculatory asthenia. If youth could be prescribed as a drug it would be the finest thing in the world for the sufferer with a senile heart. For a person is as old as the flesh of his heart and we find old hearts in young people and young hearts in old people. Age and youth blend and nobody can agree as to what age senility begins.

Harmfulness of Caffeine and Value of Alcohol in Old Age

OLIVER T. OSBORNE, M.D., F.A.C.P.
New Haven, Conn.
Professor of Therapeutics, Medical Department, Yale University,

SYMPTOMS OF OLD AGE

It is assumed in this discussion that the individual has normal old age and is not suffering from any localized or general disease. Briefly, the main symptoms of advancing age (the term senility means more than is here considered) are: slower and not perfectly coordinated movements; mental slowness with memory lapses and loss of words, often only momentary; forgetfulness of recent events; indifference to information given, unless extremely personal; more or less noticeable irregularities in eating and incoordination of eating movements so as to be mussy; insomnia; nocturia; morning polyuria; poor peripheral circulation; cold hands and feet and feeling cold even in ordinary temperatures; joint pains; stiffness; constipation; colon putrefaction; pyorrhea alveolaris; some dyspnea on ordinary exertion; often irregular cardiac pains; and the many symptoms of endocrine gland deficiencies.

It is not generally recognized that with the deterioration of all organs and functions with advancing age the endocrine glands are similarly affected.

Deterioration of thyroid secretion aggravates the normal tendency to general sclerosis; causes a shrinking and wrinkling of the skin; diminished perspiration and consequent dryness of the skin, frequently with tendency to eczema; and more or less mental apathy.

Parathyroid deficiency is shown by the hair becoming brittle and falling easily, the nails and teeth becoming brittle, and by an increased nervousness and irritability, due to imperfect calcium metabolism.

Suprarenal deficiency is shown by the tendency to pigmentations of the skin, black dots and brown patches, and by the loss of circulatory and muscle tone.

Gonad deficiency is shown by diminished sexual ability and general vitality, and the appearance (perhaps from this cause) of senile skin spots, warts, etc.

Pituitary deficiency is shown by the deposition of fat, by a tendency to glycosuria, by a tendency for the deposit of bone in cartilage, by the stiffening of joints, and, often, by kyphosis.

TREATMENT

The main factor in causing a socalled healthy old age is for the person to grow old gracefully. This means that he requires more rest hours a day, more days a month without physical labor or mental cares, and more vacation periods. It also means that during his hours away from business and during his vacation times he must not play strenuously. He must learn to relax, not necessarily to become sedentary, but to play golf or drive a machine moderately and not strenuously.

It is a mistake for such a person to give up his ordinary avocation, but he should confine his labors to his regular work or business, and cut out all side-issues and cares, such as committee work and responsible positions, whether they be political, civic, business, church or society.

The diet should be modified to meet the conditions of his work and his needs. Indigestion and bowel stasis, if present, should be corrected largely by diet. An evident glandular deficiency may require help and may many times be helped. Not infrequently small doses of iodine, as one drop a day for one week each month will be a good treatment. Focal infection, especially in the mouth, must be eradicated.

THE HARM OF CAFFEINE IN OLD AGE

The aging individual, whether he has low blood pressure or has been having high blood pressure (and generally it is becoming lower from the less strenuously acting heart) feels the need of stimulation. He has learned that he can get this from coffee and tea. But he also learns, in the large majority of instances, that coffee or tea taken at the evening meal, which for years has not prevented sleep, now causes him to be wakeful. At other meals or other times of the day, however, he is in-

clined to increase the amount of caffeine stimulation.

The action of caffeine is to increase general nervous irritability, cause palpitation, cause sleeplessness, cause cerebral irritability, cause polyuria, and especially to stimulate the thyroid and parathyroids to abnormally increased activity, with the result of more nervous irritability and muscular irritability and trembling. Caffeine often raises the blood pressure, when such an increase of blood pressure is not needed.

Caffeine (coffee and tea) in any form is likely to increase the production of uric acid, which in old people is especially likely to irritate the kidneys and to cause muscle and joint pains.

Therefore it is evident that, except in an emergency for caffeine therapeutic stimulation, coffee and tea can do nothing but increase the troublesome symptoms of old age.

THE VALUE OF ALCOHOL IN OLD AGE

A small amount of alcohol acts as a gentle narcotic to the brain, dilates the peripheral bloodvessels, gives a feeling of surface warmth and warmth to the extremities, and depletes the internal congestion areas, often starts a failing appetite, quiets an irritable heart, and gives a general feeling of comfort to these individuals.

Alcohol has a positive food value, and if sugar is added (unless sugar is contraindicated) a food is furnished that readily oxidizes and is of benefit to old people.

Alcohol as a heart stimulant in shock is of no value, but it is of great value as above described. Only an ignorant layman prohibitionist and a hypocritical physician will deny the value of a little alcohol in the discomforts and weakness of old age.

The Nutrition of the Aged

ROBERT HUGH ROSE, M.D.
New York

In order to arrive at a correct dietary for the aged, it is only necessary to modify the normal diet of the adult to make it suit the lessened activity and vitality of advanced years. Excesses of all kinds must be guarded against. The total quantity of food must be reduced to actual requirements; the different constituents of the dietary must not be permitted in amounts which would be harmful. An adult may indulge in a single dietary excess with little danger; habitual excesses show their effects slowly. To the aged, on the other hand, the former may be fatal and the bad effects of the latter are quickly manifested.

MORE THAN A MAINTENANCE DIET

A maintenance diet furnishes all the essential food elements in abundance. It does not necessarily, however, exclude excesses in one or more elements or in total quantity. A correct diet, therefore, being more than a maintenance diet, should include balance among the food elements and provide for a total quantity which is not excessive.

DIETARY DEFICIENCIES

A dietary may be deficient in many ways. Of course the well known proteins, fats and carbohydrates, must be present in abundance. We now recognize, in addition, that several vitamines are required to protect against rickets, scurvy or beriberi. A dietary deficient in iron is a possibility occasionally encountered. The American is more apt, however, to choose foods lacking in calcium than in iron or protein. In order to provide against such deficiencies it may be said, in a general way, that variety in the daily menu practically eliminates all such deficiencies. It does, providing that variety includes greens, coarse vegetables, fruit and milk. The milk is necessary as a source of calcium unless the helpings of the greens and coarse vegetables are very generous and these articles are regularly a part of the daily menu.

DIETARY EXCESSES

Various excesses in eating are especially dangerous for the aged. The kidneys show more or less impairment in function with advancing years. For this reason the protein factor in the diet must be kept as low as is safe. When the kidneys are incapable of keeping up with excretory requirements the heart and arteries are injured by toxins accumulated in the blood. Carbohydrates and fats, being associated with gastrointestinal fermentation and with acidosis, are sources of heart and kidney diseases. Diabetes is more common in the later decades of life. Pastry and rich desserts are to be avoided because they contain concentrated carbohydrates and fats and frequently protein (egg) and are generally taken when the individual is already surfeited with food. Overloading the stomach is one of the most dangerous things the aged can do. Seasonings of all kinds should be restricted, almost to the point of exclusion. The more simply our foods are prepared the better. All the dangers which occur to adults from dietary indiscretions are multiplied many times for the aged. Much of the sickness which occurs between forty and sixty, exclusive of contagious diseases, is due to faulty eating. Of those who do not succumb at this time, many are affected after sixty.

PROTEIN CONTENT OF THE DIETARY FOR THE AGED

The protein content of a suitable dietary for the aged should be as low as is compatible with adequacy. Here the work of Chittenden is especially valuable since he has proved that the adult can live in robust health on much less protein than we were formerly led to believe was necessary. No one should hesitate to give the aged the benefit of this information. Forty to sixty grams of protein daily is

an abundant provision for them. In a former (1) article I showed that we obtain between thirty and forty grams of protein from breadstuffs, cereals, fruits and vegetables—in other words, from articles classed not as proteins but as carbohydrates. This leaves, if the Chittenden standard is followed, a very small amount of protein to be obtained from the protein foods as such. It is evident, therefore, that very little meat is necessary to bring the supply up to full requirements. Some elderly people have acquired the habit of using meat only twice a week and they seem to do very well. To be more exact in our calculations, if we assume thirty grams (the lower figure) are obtained from the nonprotein class, then all the meat that is necessary daily will be the equivalent of a piece of beef five by three by one half inches (twenty-three grams protein). This gives a safe margin of protein for the aged. If no meat is taken, three glasses of milk will furnish an equivalent amount of protein. A piece of cream cheese, two by one by one inches (8.1 grams), one egg (6.3 grams) and one glass of milk (7.5 grams), would be equivalent to the above mentioned amount of meat. (See table I.)

COMPUTATION OF PROTEIN REQUIREMENTS WITH THE AID OF THE ACCOMPANYING MENU

The accompanying menu analysis shows a derivation of protein from some of the vegetables, grains and fruits. It would be difficult to select the protein in each article of food every time one recommended a menu for the day, but, taking this table as a standard and good average, one can approximate the protein in a menu with fair accuracy and simplicity. Starting with a knowledge of the approximate amount of protein in the nonprotein articles of a day's menu, the difficulty of the problem is reduced probably ninety per cent. Inasmuch as the reduction of the protein content of the dietary of the aged is of so great importance I will include from my aforementioned article the tables and some of the discussion used therewith. This day's menu includes eighty-three grams of protein, 35.5 of which were from fats and carbohydrates and 47.5 grams from proteins. To modify this for the aged the protein of the protein class should be reduced at least fifty per cent, especially through the reduction of meats.

The principal protein foods are meat (including chicken and fish), eggs, milk and cheese. These four are easy to remember and, after learning the short table, it will be a simple matter to prescribe a definite amount of protein. The following table shows the protein content of familiar amounts of these four foods.

TABLE I

CHIEF PROTEIN FOODS

Meat, 100 grams (.2 lb.)	23	grams
Eggs, 2	13	grams
American cheese, 3 x 1 x 1 inch	12	grams
Milk, 2 glasses	17.5	grams

A sample maintenance diet is also presented and analyzed. The diet furnishes approximately 2,400 calories which is quite sufficient for one engaged in a life not overactive, i.e., for the average adult city dweller. It is suitable for a person with a normal weight of 150 pounds. A menu is given for breakfast, luncheon and dinner. The protein content and caloric value of each article of food is indicated. The total protein drawn from the nonprotein foods as well as from protein foods is given for each meal and also for the day. In modifying this diet by reducing its protein content, the caloric value will be likewise lowered a sufficient amount.

TABLE II.

SAMPLE MAINTENANCE DIET

FAT AND CARBOHYDRATE CONTENT

The fats and carbohydrates should not be taken in sufficient quantity to cause gain in weight. This, however, is seldom done in the later years of life. The best method is to limit the most injurious of these, that is, sweets and rich desserts. They cause the greatest amount of fermentation. In this way the diet will be confined, largely, to the simple foods. Butter, three to five balls daily may be used with whole grain bread and potatoes. An ounce or two of cream may be used with fruit, or otherwise. Those inclined to overweight should also limit their amount of bread. The fresh breads and those not thoroughly done are most likely to cause fermentation. Patients suffering from hyperchlorhydria will do well to limit their high content carbohydrates at meals when they indulge in meats, since the acid gastric juice, a free flow of which is stimulated by the meat, checks

carbohydrate digestion by the alkaline saliva. Sweets and meats do not go well together.

MINERALS, ALKALINE BASES AND VITAMINES

The minerals, alkaline bases and vitamines must be included in the dietary for the aged, although the less the activity the smaller is the amount which would be required. Our knowledge has not progressed sufficiently to enable us accurately to measure these elements. When white bread, potatoes, cake, milk and cheese are eaten and the amount of greens, vegetables and meat is very low, there may be an insufficient amount of iron in the dietary. The tendency is rather to feed the aged on a vegetable diet. This provides for iron particularly if it includes the greens, such as romaine, spinach, dandelion and beet tops. If, on the other hand, they are placed on a semisoft diet without the green vegetables, they are in danger of this form of deficiency. The vegetable diet is again valuable in furnishing alkaline bases and vitamines as well as other minerals besides iron. We cannot speak with authority as to the possibility of excesses in these classes of foods. Perhaps information on this subject may be developed in the near future.

CONCLUSIONS

1. The best dietary for the aged is obtained by modifying the diet for normal adults to suit the lessened activity and vitality of advancing years.

2. By preventing excesses in meats, sweets, seasonings and the total quantity of food we avoid much sickness among the aged and add to their comfort as well as to their years.

3. We must also caution them against a single indulgence in overeating, such as they may be tempted to commit at the banquet or the Thanksgiving feast. There are many fatalities due to this cause.

4. We must provide the essential elements in the diet. A vegetable diet with some milk or cheese, perhaps meat in the place of milk and cheese twice a week, is satisfactory.

5. The protein content is determined by reference to accompanying tables. The Chittenden standard is used. Fats and carbohydrates sufficient to keep the weight are allowed, the sweets and rich desserts being avoided.

Senile Pneumonia

MALFORD W. THEWLIS, M.D.
New York

SYMPTOMATOLOGY

The symptoms of pneumonia differ widely according to the age of the patient. Often we see elderly people who are walking, working and eating as usual, suddenly collapse and die, the autopsy revealing the presence of pneumonia with suppuration. In the majority of instances this is the natural termination of advanced life. We should bear in mind that the symptoms are different in old age, the disease may present a peculiar clinical picture, and if we are not extremely careful the patient will die before a diagnosis is made. After an accident, or any disease which keeps an aged patient in bed, looms up the ever present danger of pneumonia. It sometimes follows senile bronchitis and frequently fracture of the hip. It appears also after ether anesthesia.

We do not get the classical picture of pneumonia; the fact that the patient has no febrile temperature, no increased pulse rate, often misleads us; we wait for the rusty sputum and there may be no sputum at all, no chill, no pain. Two facts alone seem to stand out: one is that the respirations are increased and the other that the patient is failing rapidly. The face is usually red and the tongue dry; the crepitant râle coarser than in the adult. Because the urine often shows albumin, many erythrocytes and granular casts, we might be led to believe that the condition was due to nephritis. Senile patients suffering from carcinoma or other incurable diseases often die of pneumonia.

Pneumonia is one of the most fatal diseases of old age and it is important to give special attention to it. There are certain anatomical and physiological differences between the lungs of the adult and those of the aged. According to Loomis, the pathological changes in old age are modified by the rarefied condition of the lungs, the dilatation and rupture of the air cells, their diminished elasticity and the obliteration of large numbers of their capillary vessels. The lungs in the aged are of an ashy gray color; the surface of the pleura is less moist than in adult life. The fissures between the lobes change their position so that in the left lung the upper lobe is in front and the lower behind, and in the right lung the middle lobe projects downward, the lower one rising behind it, forming a considerable portion of the summit of the lung; therefore, pneumonia of the apex may in reality be in the lower lobe. Microscopically, the air cells are about twice the size of normal adult lung cells.

MORBID ANATOMY

The morbid anatomy of the disease consists of three stages: a stage of engorgement, of red hepatization and of gray hepatization. Gangrene is much more frequent than in the adult type. On account of the rarefied condition of the lungs in old age small abscesses are apt to develop and we sometimes see them interspersed throughout the consolidated tissue. Larger abscesses, resulting from the coalescence of several smaller ones, are not so frequently encountered in old age. The minute bronchi are usually involved.

TEMPERATURE

An aged patient who is failing rapidly should be looked upon as likely to have pneumonia. With an

increase in the respirations and delirium, the diagnosis seems evident. The patient often hits his chest with his hands as if he were in distress. Sometimes the temperature and the pulse rate are normal; in fact, they are in many other diseases of old age; a subnormal temperature is still more common. However, temperature by rectum may show an increase to 103-104° F., but this does not come before the third day. The rate taken at the heart is often different from that taken at the radial artery and owing to the sclerotic condition of the radial arteries the pulse is unsafe as a diagnostic and prognostic sign, therefore it is always advisable to take the rate at the apex of the heart. Ordinarily, the pulse rate is more frequent than at maturity. Sometimes we find a slow pulse rate in health. Loomis asserts that the normal pulse rate for old men is from 60 to 70 a minute while in women it is from 68 to 78. In contrast to the full pulse of adults, in senile pneumonia the pulse has, normally and in disease, a fictitious hardness. A pulse rate of 120 or more may not mean danger.

AUSCULTATION FINDINGS

Sometimes the findings upon auscultation are uncertain; careful examination will reveal an area of consolidation, the râles are usually coarse. Pulmonary edema, so often encountered in old age and due to various causes, may cover the classical signs of pneumonia. If we depend upon our experience in examining the lungs of adult patients we shall be deceived greatly by the variations inherent to the lungs of aged persons. In old age, it has been noted that bronchorrhea is normal and this gives rise to mucous râles which may be present at all times in senility. The respiratory murmur may be loud at one moment and at other times difficult to hear.

COUGH

The cough may pass unnoticed and if expectoration comes at all it may appear late in the course of the disease. Violent coughing may enable the patient to expectorate the characteristic sputum. Perhaps the reason why we do not see the pathognomonic sputum more often is because in advanced life there is a rapid transition of the stages, early suppuration often occurring.

UREMIC SYMPTOMS

Early in the course of the disease the senile patient becomes semicomatose or comatose and the disease may have the appearance of uremia. The differential diagnosis is sometimes difficult because in the course of senile pneumonia the urine is often scanty, bile pigments and albuminuria are present, hyaline and granular casts and blood are frequently seen. If we are not careful this will lead us to wrongly diagnose uremia.

DIAGNOSIS

To sum up, the rapid decline of the patient, together with increased respirations and delirium, suggest the diagnosis of senile pneumonia. The condition, however, should not be confused with senile bronchitis, pulmonary congestion or pleurisy. These conditions, except pleurisy, are common in old age and are often mistaken for pneumonia. The senile patient suffering from pneumonia is usually more ill than the one who has bronchitis or pulmonary congestion; however, this is not an absolute rule, because, to repeat, we may find ambulatory cases of pneumonia, where the patient carries on until he collapses.

In old age the asthenic form of the disease is observed frequently and is characterized by insidious onset, early delirium, prostration, stupor, tendency to adynamia and collapse. Death may happen before a diagnosis is made. Again, we sometimes see a so-called typhoid state with pneumonia, this is also misleading, but we should remember that typhoid fever itself is rare in old age.

It is not always possible to type the sputum because in many instances there is none to be obtained; this may prevent the early diagnosis of the disease. Through the precipitation test, it is possible to get a reaction, thus typing the pneumococci from the urine within twelve hours after the initial chill. Ordinarily, the percentage of incidence of infection with these groups is averaged as follows (Webster): Group I, 33 per cent.; Group II, 33.5 per cent.; Group III, 12.5 per cent.; Group IV, 20 per cent. Most of our senile cases seem to belong to Group III. Because of the difficulty in obtaining the sputum for bacteriological examination, great stress should be placed upon the clinical diagnosis.

PROGNOSIS

The prognosis is always grave; the toxemia resulting from pneumonia causes extreme prostration; usually the kidneys are involved and the heart is not able to stand the strain, especially since this organ has undergone senile changes. When the disease is confined to the lower lobes, some observers have claimed that the prognosis is much better and it is more favorable when there is not delirium and when the heart action is regular. The infection itself brings about pathological changes in the heart muscle.

TREATMENT

Bedridden senile patients seldom recover. If the aged patient is able to leave his bed, we should urge him to, of course; this is not possible in cases of extreme prostration.

The physician must use his own judgment but he should remember that hope is one of the strongest psychic stimulants known. Often, when we have exhausted our therapeutic measures, the only thing we can actually do for a patient is to instill into him hope and the will to live. In old age encouragement is all the more necessary because death may have become an obsession. Too often there is no cooperation between the patient—and even the patient's family—and the physician; the patient looks upon his illness as likely to be the end. In many instances I have forced patients suffering from senile pneumonia to sit in a chair and they seemed to improve as soon as this change was made, breathing became less difficult and the circulation usually improved.

If the sputum shows it is a type I case, type I serum should be used, but early diagnosis is imperative because if the serum is not given within the first forty-eight hours of the disease, it will have little effect.

The care of the senile patient is extremely important, good nursing an absolute necessity. The

patient should be turned frequently; a liberal diet should be allowed, together with plenty of fluids. The toxemia developing during the course of pneumonia often causes death, and this toxemia should be prevented as much as possible by attention to the intestinal tract. A cathartic should be given the first day, and after that it is advisable to insist on an enema each day for the first three days. Milk of magnesia or mineral oil given every night may prove satisfactory and make enemata unnecessary but saline laxatives should be avoided as they cause depletion.

The nature of the toxemia is not at all times obvious; often the kidneys are involved and nitrogen retention is found. A nonnitrogenous diet should be given in these cases. Acidosis is also frequently present in the course of pneumonia and should be counteracted by the administration of sodium bicarbonate. However, it is necessary to estimate repeatedly the carbon dioxide combining power of the blood in order not to give the alkali too long. In other instances, the toxemia seems to be due to lack of proper elimination through the intestines. This is often caused, partly, by the previous existence of chronic intestinal autotoxemia. Furthermore, the toxemia may be due to a true pneumococcemia.

Rest is of prime importance in the treatment of senile pneumonia and this is insured by infrequent examinations at the bedside. No external applications are necessary. There should be no confusion in the sickroom or around it. The ventilation should be perfect and constant. The matter of the fresh air treatment is one which can be decided for the individual patient; if the cyanosis and respiration improve on the fresh air treatment, it may be advised.

The question of oxygen administration is still open to discussion. Perhaps in some instances it is valuable and we should always be prepared to administer it if we have to. At least forty per cent. oxygen should be used and this should be given by means of the rebreathing apparatus.

Digitalis should be prescribed early in the course of the disease, beginning when there is slight arrhythmia, cyanosis and edema. One to two drams of the tincture may be given in twelve hours. Some clinicians use digitalis at the onset of the disease. The toxemia due to pneumonia weakens the heart muscle and it is thought that cardiac dilatation occurs less frequently under digitalis medication. Quinine often gives satisfactory results in old age and one grain every three hours may be used if urinalysis is normal.

Whiskey should be given as a food and its full physiological effect should be obtained. One half ounce every two or three hours, until a red spot appears on each cheek, may be given, especially as long as the tongue remains moist. A dry tongue in the course of whiskey administration usually indicates that it is harmful (Sydney Ringer). Morphine and antipyretics are usually unnecessary. Turpentine stupes and glycerine enemata will relieve tympanitis, if not severe; when this symptom is acute, pituitrin hypodermically is indicated.

Strychnine should be given because of its effect on the bloodvessels, and it should be prescribed on the third or fourth day of the disease. At first one sixtieth grain should be given every three hours, increased to one thirtieth grain at the time of the crisis. Oil of camphor may be used hypodermically when quick action is required; the effects of camphor are not lasting, but some believe it is of value in toxic conditions. Adrenalin may be given, however, we should not wait for extreme vasodilatation before giving it. Cardiac exhaustion, evidenced by increase in the pulse rate and lowering of blood pressure, calls for adrenalin.

The pulse, in old age gives little indication for treatment, because a pulse of good quality may not indicate good circulation while with auricular fibrillation the circulation may be good. Auricular fibrillation frequently accompanies senile pneumonia and in treating this condition, we usually find digitan satisfactory.

PREVENTION

Thus far nothing has been said about the preventive treatment of senile pneumonia. Among the predisposing causes of infection, chilling of the body surfaces affecting the circulation in mucous membranes, is important. Rosenow has also shown that chilling may increase the pathogenicity of bacteria in the tissues. The removal of focal infection, especially in the tonsils or nasal accessory sinuses, is a valuable prophylactic measure. Warm clothing should be worn and fatigue avoided. Care should be taken not to expose the aged to socalled colds or influenza. In a home where there are aged people, persons suffering from respiratory infections should be isolated. In treating accidents, such as fractures, sprains, etc., when the patients are in bed, we should see that they are turned on their sides several times a day in order to prevent pulmonary hyperemia.

SUMMARY

1. Pneumonia presents a peculiar clinical picture in senility.
2. The ambulatory type is sometimes observed.
3. Pneumonia is a natural termination of an old person's life.
4. Senile patients seldom have fever or increased pulse rate; increase in respiration, prostration and delirium point to pneumonia.
5. Senile pneumonia should not be mistaken for senile bronchitis or pulmonary congestion.
6. The asthenic form of pneumonia is frequently seen in the aged.
7. Difficulty of typing pneumococci is encountered because there is often no sputum.
8. The prognosis is always grave.
9. Keep senile pneumonia patients out of bed whenever possible.
10. Good nursing, liberal diet, plenty of fluids and rest form the basis of treatment.
11. Catharsis to prevent toxemia.
12. Presence of nitrogen retention and acidosis common.
13. Rest of prime importance; infrequent examinations, digitalis, whiskey and strychnine advised.
14. Preventive treatment: warm clothing; no chilling of body surfaces; removal of foci of infection; avoid exposure to common colds; turn patient several times a day when in bed as a result of fracture, etc.

114 East Fifty-fourth Street.

Decrescent Arteriosclerosis

ERNST P. BOAS, M.D.
New York
Medical Director, Montefiore Hospital for Chronic Diseases, New York.

Arteriosclerosis is a complicated process and one about which there still is much to learn. Consequently, its clinical manifestations are not always clearly understood, and the term itself is often applied loosely to conditions to which it bears no relationship. Arteriosclerosis itself has been best defined by Jores, who states that "Arteriosclerosis is a complex process in which degeneration and compensatory regenerative hyperplasias of the vessel wall are closely associated. It leads to dilated and tortuous arteries, the inner layers of whose walls become thickened either diffusely or in circumscribed areas, in which lipoid, hyaline and mucoid degenerations, as well as calcification, may occur at one and the same time."

In spite of innumerable painstaking and ingenious experiments, the causes of this obscure malady are still unknown, although a few leads have been discovered which may, however, be interpreted in only the most general way. The two chief influences at play in the causation of arteriosclerosis are, first, mechanical stress, and, second, metabolic disorders. Many observations point to the importance of mechanical moments in the evolution of arterial disease. As illustrations, we may use the peculiar and characteristic localization of the early atherosclerotic lesions in the aorta about the mouths of the intercostal arteries; just above the semilunar valves, and at the convexity of the aortic arch—all places which we may presuppose are subject to particular stress and strain; the occurrence of localized sclerosis in vessels of a limb which has been subjected to unusual and persistent muscular work; the development of sclerosis of the pulmonary artery in patients with increased pressure in the lesser circulation (mitral stenosis, emphysema). By analogy it has been supposed that, with advancing years, although the stresses to which the vascular system is exposed may not be exaggerated, the aging heart and vessels experience even the ordinary demands of daily existence as an overload, and react in the same way as do vessels which are subjected to abnormal strains.

The belief that metabolic disturbances may influence the development of arteriosclerosis depends on the fact first demonstrated by Anitschkow, that cholesterin feeding will produce arteriosclerosis in animals. It has further been shown that mechanical moments acting at the same time influence the location and extent of the atherosclerotic lesions. Infectious diseases are factors in the development of arterial lesions most probably through their effect on the cholesterin metabolism.

Yet it must be repeated that the detailed application of these general principles still escape us. For example, every attempt to demonstrate in patients with arteriosclerosis a disturbance of the cholesterin metabolism, as evidenced, for instance, by abnormally high figures for the blood cholesterin, have failed. Overeating, especially of nitrogenous food, alcohol, tobacco, are all generally listed among the causes of arteriosclerosis, but there is no direct evidence supporting this assumption. Of the exogenous poisons, lead is the most important one for which a causal relationship to arteriosclerosis has been established.

In this presentation we shall confine ourselves to disease of the larger vessels of the body, but leave out of consideration the delicate fat deposits in the intima which may occur in the very young. Disease of the arterioles, the socalled arteriolosclerosis, while it may be explained by the same general principles that we have detailed above, is fundamentally different in its clinical manifestations. It is invariably associated, and most probably the consequence of hypertension, and by and large it occurs at an earlier age period than arteriosclerosis of the larger vessels.

This voluntary delimitation of our field leads at once to a consideration of the relationship between arteriosclerosis of the larger arteries and high blood pressure states. It must be clearly and definitely understood that the weight of evidence points to the fact that large vessel sclerosis and hypertension bear no causal relationship to one another, although not infrequently they may be associated in the same individual. This idea is hard to uproot, although it has been repeatedly combated by various wellknown clinicians. Sir Clifford Allbutt has been one of the chief champions of the doctrine of the independence of arteriosclerosis and hypertension and he has attempted to clarify the subject by designating those cases of arterial disease which occur in older individuals and which are unassociated with hypertension as decrescent arteriosclerosis. Careful observation by the physician in his daily practice will confirm the correctness of these views. Another significant fact which clearly differentiates hypertension from large vessel sclerosis is the varying age incidence of the two affections. Hypertension occurs chiefly in the years from forty-five to sixty-five; significant large vessel sclerosis is found predominatingly in patients above the age of sixty-five.

Arteriosclerosis does not involve all of the arteries of the body to an equal extent in every patient. Indeed, the distribution of the lesion varies greatly in different individuals. The following table from Brooks gives a general idea of the frequency with which the lesions are found in the several regions of the body. In all but thirty cases lesions were found in the arteries of more than one viscus.

	No. of Cases
Total	400
Aorta	301
Visceral trunks	368
Coronary arteries	270
Brain	132
Kidneys	81
Pancreas	74
Liver	43
Spleen	35
Celiac axis	19

The symptoms of arteriosclerosis depend on the diminution in the blood supply of the part affected. This may be of varying degree. At first there is no interference with function, but as the arterial disease progresses, a time comes when the blood supply to a given part is no longer adequate during moderate functional activity, although it may suffice when the part is at rest. Thus arise symptoms such as intermittent claudication of the limbs, which appear only on effort. As the pathological process progresses, and as gradually complete vascular occlusion occurs in limited areas, tissue death with fibrous replacement occurs. This is seen in the various viscera, particularly in the heart and kidneys, and in the brain. Thrombosis of a larger vessel may suddenly cause loss of function of a larger area, as happens not infrequently in the cerebral arteries.

DIAGNOSIS

The diagnosis of visceral disease due to arteriosclerosis is always difficult, and can usually be only presumptive. The explanation of symptoms or of disease in elderly individuals by the use of the terms general arteriosclerosis or cerebral arteriosclerosis is more often than not unjustified. Unfortunately, the visceral arteries are not accessible to the palpating finger, and their calcification can rarely be demonstrated by the röntgen ray. Moreover, careful study of necropsy material has shown that hardening of the peripheral arteries, such as the radial, which are accessible to physical examination is not necessarily paralleled by similar involvement of the visceral branches. Brooks, for instance, found that of his four hundred cases of arteriosclerosis proven at autopsy, only 154 were capable of clinical diagnosis. Furthermore, in eight of the cases there was marked peripheral arteriosclerosis, while the central vessels were absolutely intact. The diagnosis of arteriosclerosis of any particular organ, therefore, must be made with great caution, and only after every other possible pathogenic agent has been excluded. The age of the patient is of great weight. After the age of sixty-five the correctness of the diagnosis becomes more and more probable. In individuals under the age of fifty there must be widespread evidence of arterial disease, and possibly a history of familial predisposition to justify the diagnosis.

SYMPTOMS

The symptomatology of arteriosclerosis depends on the regions of the body that happen to be affected and can, therefore, be discussed to advantage under the heading of the various organ systems.

GENERAL ARTERIOSCLEROSIS

This is the diagnosis most frequently encountered and the one that is most open to question. If an elderly individual presents evidence of thickened and tortuous superficial arteries such as the radials, temporals, femorals, his symptoms, whatever they may be, are often attributed to arterial disease. While it is true that at times this may be correct, not infrequently the arterial disease cannot be held responsible. In the aged, widespread calcification of the superficial vessels may be manifest for years without giving rise to any symptoms, and without causing any distress. Arterial disease of equal extent in a younger person, on the other hand, is of grave import, for it signifies a rapid and progressive lesion. One of the reasons why the aged are often so little troubled by their arterial disease is the fact that they place such light demands on their cardiovascular system. They are retired from active life and engage in little physical exertion. The same person placed in a position in which he would have to undergo severe physical strain would probably manifest symptoms of functional insufficiency of one or more of his organ systems. So long as there is no serious impairment of blood supply to any of the important viscera, the patient is little disturbed by the senescence of his arteries. Rarely one sees such a person undergo a rapid and progressive cachexia, the so-called arteriosclerotic cachexia, which leads to an early death. Such an event can justly be attributed to general arteriosclerosis, for there may be no indication of any visceral insufficiency; it is rather a rapid wasting away of the whole organism.

BRAIN

Cerebral arteriosclerosis gives rise to a very familiar picture. The forgetfulness, the headache vertigo, fatigue, and somnolence of the aged is often traceable to advanced disease of the cerebral arteries. In time the picture may progress to that of complete mental deterioration, with returning childishness, incontinence of bladder and rectum, and the loss of all former standards of cleanliness and decency. Disturbances of mental equilibrium with fits of laughter and weeping are very characteristic. These general symptoms ordinarily come on insidiously without evidence of sudden vascular insults and are attributable to many small areas of cerebral softening consequent on vascular obliteration without actual apoplexy. More often thrombosis of one of the cerebral vessels, particularly of the branches of the middle cerebral artery, occur. In such cases there is evidence of a definite apoplectic stroke with resulting hemiplegia. In contrast to the apoplexy from rupture of a blood vessel, which is usually associated with hypertension, the onset of symptoms is often gradual, stretching over twelve to twenty-four hours. Isolated monoplegias and aphasias are distinctive of thrombosis rather than of hemorrhage. These patients frequently present the syndrome of pseudobulbar palsy, with incomplete bilateral hemiplegia and disturbances in phonation, deglutition, and, at times, of respiration.

HEART

Heart disease, following sclerosis of the coronary arteries, is extremely common, but is often difficult of diagnosis. It is rare to find in older patients who come to autopsy coronary vessels that are free from some degree of sclerosis, but the correlation between the degree of insufficiency of the heart muscle and the exent of the anatomical lesions is not close. Failure of the heart must be determined just as much by invisible metabolic or chemical perversions as by the visible lesions that present themselves at necropsy. Many patients with myocardial degeneration consequent on gradual closure of the coronary arteries exhibit no symptoms of cardiac disease during life. In others pallor, general weakness and ready fatigue are the only observable symptoms. The facies are

often characteristic—an earthy pallor with an expression of sorrow or pain.

With greater involvement of the heart muscle signs of myocardial insufficiency become manifest. At first palpitation, precordial oppression, and dyspnea on exertion are the presenting symptoms. Swelling of the feet, congestion of the lungs and liver, and the other signs of advanced myocardial weakness may make their appearance. Nocturnal dyspnea is often distressing. The attacks may be very severe, resembling bronchial asthma. In the intervals cough and wheezing in the chest may be the chief complaints. In examining the patient the determination of the absence of evident causes for the heart failure is more important than any one positive sign. There may be no valvular lesion, there is no history of rheumatic fever, no evidence of syphilis, and the blood pressure is often normal. The heart may be enlarged, a systolic murmur is often heard at the apex due to a relative mitral insufficiency, or to an arteriosclerosis of the valve. In the late stages of the disease gallop rhythm is common. A systolic murmur at the second right interspace and a widening of the area of aortic dulness may indicate the associated presence of an ateriosclerotic dilatation of the aorta. The heart impulse is feeble in contrast to the full pulse. The latter is due to the inelasticity of the arteries. Arteriosclerosis of the peripheral arteries may or may not be manifest.

DISORDERS OF RHYTHM

When the scars involve the conducting system of the heart disorders of rhythm appear. Of these, auricular fibrillation and premature beats are the most frequent. Often the fibrillation is slow because of a concomitant heart block which prevents most of the auricular impulses from reaching the ventricles. In such cases the irregularity adds little to the gravity of the case. Heart block, complete or partial, and the Stokes-Adams syndrome are relatively uncommon in this form of heart disease. Block of the ramifications of the conducting system, which can be detected only by the electrocardiograph, however, is not at all unusual and gives the best objective evidence of myocardial degeneration. Alterations in the electrocardiogram often give the only objective clue to this lesion. It is in these patients that tracings described as arborization or intraventricular block are most often encountered. Such electrocardiographic evidence associated with the clinical picture is of great assistance in diagnosis, although it must be remembered that these abnormal tracings give evidence only of disturbances in the finer ramifications of the conducting system of the heart and do not indicate the nature of the pathological lesion.

The clinical picture that has just been described is associated with a slow insidious closure of the branches of the coronary arteries. Sudden closure, due to thrombosis, results in more violent and dramatic symptoms. In many of these patients the above symptoms precede the acute insult for a variable period. On others the coronary attack descends like a thunderbolt from a clear sky.

The cases fall in several clinical groups. In one death is almost instantaneous, often painless and peaceful. The diagnosis can be only presumptive, based on the previous symptomatology, and on the knowledge of the frequency of this occurrence in older individuals. In the second group of cases severe pain of the nature of angina pectoris, associated with symptoms of profound shock, followed by death in several minutes or hours, characterize the attack.

THE ATTACK

The charactertistic feature of the attack is its sudden violent onset. In some cases there may be premonitory symptoms, such as dyspnea and tightness in the chest for days and weeks preceding the seizure, but in others there is no warning. The patient, who is usually beyond middle age, is seized with a violent constricting retrosternal pain, which may remain localized or may radiate to the left arm or to the neck and cheek. Not infrequently the pain is epigastric and with this there may be some rigidity of the upper abdominal muscles. This, in association with the frequent occurrence of vomiting or meteorism, may lead to the mistaken diagnosis of a perforated gastric ulcer or some other acute abdominal condition. Indeed, most deaths from socalled acute indigestion are due to coronary closure. With the pain the symptoms of shock make their appearance. The skin assumes an ashy pallor, there is a cold sweat, the pulse is feeble. The patient experiences a sense of impending dissolution. The mind usually remains clear.

The heart sounds are weak. This is due in part to the enfeebled heart action, in part to the acute emphysema of the lungs, which so commonly occurs with the attack. In many cases a friction rub may be heard giving evidence of the localized pericarditis that so frequently overlies the area of cardiac infarction. The pulse is small and thready and may be irregular due to extrasystoles or to heart block. Some cases exhibit paroxysmal ventricular tachycardia with a pulse rate from 170 to 250 a minute. Electrocardiographic studies may give curves corresponding to those described under myocardial degeneration. The blood pressure is low. In addition to the signs of emphysema the lungs show râles at the bases. Dyspnea is a common feature. The liver enlarges. Fever and polymorphonuclear leucocytosis are usual and add to the difficulty of distinguishing these cases from acute surgical accidents.

The outcome of the attack is variable. Some patients rapidly succumb. Others may survive several hours or even days, and a few may recover from the attack. In those cases in which death is not immediate the suffering of the patient may be terrible. This is the real status anginosus with excruciating heart pain lasting many hours. The patient is afraid to move for fear of increasing his anguish. In some cases with violent onset the pain gradually recedes, but the patient is left weak and exhausted and in dread of renewed attack. Death, if it does not come in a paroxysm of pain, is due to progressive heart failure. The pulse becomes weaker and more thready, Cheyne-Stokes respiration sets in and life is gradually extinguished. Recovery, if it occurs, is slow and may be cut short by a renewed seizure. The first attack of coronary thrombosis almost invariably involves the left coronary artery, usually its descending branch. When a second one occurs, be the interval one of days or months, it is fairly safe to

hazard the guess that it is conditioned by a like involvement of the right coronary vessel.

The few patients who recover may be restored to comparative health and may lead a fairly active life before a second attack or a rupture of the heart determines the end.

AORTA

Arteriosclerosis of the aorta is extremely common. The process involves not alone the arch and the thoracic portion, but very frequently extends to the abdominal aorta. These patients may be classified into those in whom there is simple involvement of the aorta, those in whom the process has involved the aortic valves as well, and those in whom the coronary arteries are encroached upon.

Advanced sclerosis of the aorta results in dilatation and lengthening of the vessel. This is evidenced by increased dulness in the first two interspaces to the right of the sternum, by pulsation in the jugular notch, and by pulsation of the subclavian artery above the clavicle. The heart is not enlarged, the second aortic sound is accentuated, and there is usually a systolic murmur audible at the aortic area. Radiographic examination may reveal, in addition to a widening of the transverse diameter of the aorta and an elevation of the arch, definite shadows of calcified plaques.

When the semilunar valves are included in the atherosclerotic process the symptoms and signs of aortic insufficiency are superadded. Aortic stenosis may develop in contradistinction to syphilitic disease. When the orifices of the coronary arteries are sclerosed attacks of angina pectoris may occur. When this happens the prognosis becomes grave. Either the patient dies from acute coronary closure, or else the impaired nutrition of the heart muscle and the frequent closure of smaller branches of the vessels cause myocardial degeneration, with progressive myocardial insufficiency. The myocardial lesions may cause cardiac irregularity. Auricular fibrillation is the most frequent arrhythmia encountered.

Arteriosclerotic disease of the aorta is of slow development and often causes few symptoms. Even when aortic insufficiency develops, they may be insignificant. Coronary artery disease is the most frequent cause of distress in these patients. But even in these cases we have learned that if the occlusion of the vessels is a very gradual one, large areas of heart muscle may be destroyed without causing the patient very great inconvenience. The anastomoses of the coronary arteries, in particular the fat vessels in the epicardium, are able to carry on a circulation sufficient to the restricted needs of the individual.

Death comes from myocardial insufficiency or from intercurrent disease.

The loss of elasticity of the aorta has an important effect on the dynamics of the circulation and results usually in the elevation of the systolic blood pressure with little change or, at times, even with a lowering of the diastolic pressure. The common reading in this condition would be 160/80 or 145/70. Such readings must be clearly differentiated from true hypertension, in which the diastolic pressure is always elevated and which is associated with sclerosis of the finer arterioles.

KIDNEYS

Arteriosclerosis of the larger branches of the renal arteries gives rise to gross scarring of the kidneys, but not to the typical granular kidneys. Not enough kidney tissue is destroyed seriously to impair their function, and consequently no symptoms of renal insufficiency are apparent. The lesion therefore is of no clinical importance and cannot be diagnosed.

GASTROINTESTINAL TRACT

Disorders of digestion resulting from interference with the blood supply of the intestinal tract have been described by various authors, but the relationship between symptoms and anatomical lesions has not been conclusively demonstrated.

Ortner has described attacks of meteorism with nausea and vomiting occurring after meals and lasting several hours, which he attributed to sclerosis of the mesenteric arteries and which he called *dyspragia intermittens angiosclerotica intestinalis*. Other authors have included in this general symptom complex the lesser forms of indigestion in elderly individuals with arteriosclerosis and have likened them to attacks of intermittent claudication of the extremities. It is supposed that the diseased mesenteric vessels do not furnish an adequate blood supply to the intestines during the process of digestion. Thrombosis of the mesenteric artery, which, fortunately, is uncommon, may definitely be attributed to arteriosclerosis of the vessel.

EXTREMITIES

Arteriosclerosis of the vessels of the extremities is readily recognized. One must be careful, however, to distinguish between an artery that is spastically contracted, and which therefore feels thick, and one that is thickened by disease. The spastic vessel will undergo variations in calibre at different times and can be relaxed by placing the member in hot water. Thickening of the peripheral vessels may exist in all degrees from one so slight that it can barely be appreciated, to complete calcification and incompressible rigidity. It is in the peripheral vessels, particularly in those of the lower extremity, that Mönkeberg's medial calcification is so often found. This can be beautifully represented by means of the röntgen ray. It is only rarely that it causes the patient any disability. The most characteristic symptoms of sclerosis of the vessels of the extremities are those of intermittent claudication. On walking the patient experiences severe pains in one or both of his legs, which compel him to rest. After a short period of inactivity the pains disappear but recur when the limb is again exercised. Physical examination may reveal thickened femoral or popliteal arteries which may show evident calcification on the röntgen plate. In other cases pulsation of the posterior tibial or dorsalis pedis vessels cannot be felt.

Not every case with advanced sclerosis of the arteries of the leg presents these symptoms, and it seems probable that anatomical narrowing of the arteries alone will not account for the intermittent pain. It is suggestive, as was pointed out by Erb, that these symptoms are more common in nervous persons, particularly in those with a labile vasomotor

system. It seems likely that a spasm of the vessels is an additional factor in the production of the syndrome. This view is supported by the fact that during the attack blanching and coldness of the affected limb occur, and disappear with the relief of the pain.

With more advanced arteriosclerosis of the arteries, particularly in that form known as endarteritis obliterans, gangrene of the toes or even of the leg may appear. This gangrene may be initiated by trauma, or may be associated with a general disturbance, such as diabetes mellitus.

TREATMENT

Therapy in arteriosclerosis can be only symptomatic. There is no known form of treatment that will control the progress of the arterial lesions. On general principles it is wise to plan a quiet temperate life for the patient. No particular dietary restrictions beyond moderation, with a tendency to undereating rather than overeating, are indicated. Medicaments such as potassium iodide are without effect. Beyond this, attention must be directed to the various organ disturbances which must be handled symptomatically. For the cerebral manifestations little can be done. It is most important following an apoplectic seizure to reeducate the patient as soon as possible, and to teach him to walk again before advanced contractures render his limbs useless. In the treatment of arteriosclerotic heart disease, the general principles of cardiac therapy are employed.

Symptoms due to sclerosis of the arteries of the extremities must be treated conservatively. Rest is all important, and in association with this elevation of the affected limb is often of benefit. Hot air baking of the limb should never be employed, for it often initiates gangrene. Of the physical methods of treatment diathermy is the most valuable. In selected cases, Leriche's operation of periarterial sympathectomy may be indicated. With the onset of gangrene expectant treatment should be followed as long as possible, for often, particularly in dry gangrene, a clear line of demarcation forms, the gangrenous portion is cast off and healing takes place. If operation becomes necessary, the amputation should be well above the site of vascular occlusion.

Local and Regional Anesthesia in Operations Upon the Aged*

A Review of One Hundred Operations

J. LEWIS AMSTER, M.D.

New York

In a recent editorial, entitled Old People, Dr. Frank Crane remarked: "Just being old is one way to attain distinction. It is hard work, but it can be done if we stick to it long enough."

Humboldt, in the course of his travels, was present at the funeral of a Peruvian called Hilario Pari, who had passed the age of one hundred and forty-three years. Up to his one hundred and thirtieth birthday, this vigorous old boy walked every day, some three or four leagues at a lively pace, which worried the younger men, and they apparently had a hard time to keep up with him. And then, of course, there is Methuselah—but that is another story.

The aged person who must become the subject of operative surgery is also another story—at least to the surgeon who operates. The problems and pitfalls attending all operative work are complicated and intensified, when we must deal with a patient past middle life—no matter how strong and vigorous he may appear to be. And the greater the decline of his powers, and the more marked the advance of senility, the more difficult will the solution of the problem become.

Walter Brickner, in an editorial in *The American Journal of Surgery*, writes: "Some patients at seventy are feeble, physically and mentally, as many at ninety, and on the other hand, some people at eighty are as vigorous and heathly as the average at seventy. We should therefore consider as aged those who are very old in their tissues and functions, no matter how old they may be in years." Thus the surgeon's problem is still further complicated, for not infrequently he must detect in those still relatively young in years, "the tissues and functions" of the aged, and guide his procedure accordingly.

There are many patients whose treatment by surgery is imperative, upon whom the use of a general anesthetic is absolutely contraindicated. When shock or other cause has greatly lowered the vitality, or kidney or heart affections are present, the additional strain of general anesthesia is sure to prove fatal, and in old age we are very likely to find conditions which are quite as effective drawbacks to the use of a general anesthetic.

In operating upon old people, we should keep in mind their lowered resistance and poor tissue vitality. Any such operation should always be regarded as a serious undertaking, and the prognosis should be very guarded if general anesthesia is to be administered. The operative risk is now considered far less, if local or conduction anesthesia is used. The advantages of this method are selfevident and are manifested in many ways.

Until recently, the method of infiltration and block anesthesia was looked upon by many surgeons as such a complicated and difficult procedure, that it was rarely used in major operations. But this reluctance, on the part of some surgeons, served to give many of the less intensively conservative, a most unusual opportunity to concentrate their efforts and

attention upon this new field of surgical anesthesia, so that today, local and conduction anesthesia is being administered with marked success in many major operations.

Since cocaine has been replaced by the newer synthetic compounds, possessing relative nontoxic properties, the use of infiltration and regional anesthesia has become the method of choice in operations upon the aged. The more serious surgical conditions arising in old age, once believed to be inoperable and absolutely hopeless, because of the risk and danger of general narcosis, can now be remedied, the pains and sufferings of old people which require surgical relief need no longer go without alleviation, and the duration of life can very frequently be greatly extended by the surgeon's aid.

Strangulated hernia is a condition that is not infrequently present among elderly people—a hernioplasty under local or regional anesthesia is usually carried out successfully if the strangulation is less than six hours' duration.

Even though local anesthesia is still in its infancy, it is rapidly supplanting general anesthesia in major operations upon the aged. The gratifying results both to the patient and the surgeon have prompted some operators to extend this form of anesthesia among young patients in whom ether narcosis is contraindicated. Notable advances in this work have been made by Allen, Corning, Crile, Cushing, Halstead, Hertzler, Labat and Matas of this country, as well as Barker, Braun, Finsterer, Hirschel, Recleus, Schleich and others abroad. Men of this calibre, as the result of their vast experimental and clinical experience, developed especial skill in the administration of infiltration and regional anesthesia, are steadily becoming more proficient in their technic and more certain in their results.

RADICAL OPERATIONS UNDER REGIONAL ANESTHESIA

1. Allen and Matas, in referring to local and regional anesthesia, lay special stress on the success that they had obtained in the invasion of the newer fields of surgery. With block and infiltration anesthesia, they were able to do radical operations on the tongue, resections of the jaw, thyroid and larynx. Amputations of extremities, resections of joints, thoracotomies and hernioplasties were also successfully performed. In fact, the entire domain of genitourinary, rectal and a considerable amount of abdominal and pelvic surgery became amenable to the new methods.

ABDOMINAL OPERATIONS UNDER INFILTRATION ANESTHESIA

2. Robert E. Farr, of Minneapolis, who recently related his experience in nearly two thousand operations under local anesthesia, says that he considers the direct infiltration method an ideal one in abdominal surgery. With this process he was able to perform eighty per cent. of all the abdominal operations that came into his hands in the past six years. That the administration of general anesthesia, in skilled hands, is an absolutely safe and harmless procedure, is an assertion sometimes uttered by an overenthusiastic or inexperienced general anesthetist or surgeon. No matter how carefully or skillfully general narcosis is given, there is always the danger of unforeseen complications, and sometimes accidental death, which may be attributed directly or indirectly to the effects of the ether, chloroform, or nitrous oxide used to obtain anesthesia.

RECTAL OPERATIONS UNDER ETHER ANESTHESIA

3. W. O. Hermance, of Philadelphia, reports six thousand rectal operations with ether anesthesia, without a single death or without having to resort to resuscitation. Not very long ago one of our anesthetists of this city claimed to have administered forty thousand ether anesthesias without a casualty. If I were asked to venture an opinion regarding these remarkable assertions of general anesthesia I would say that the Lord was unusually kind to these gentlemen.

MAJOR OPERATIONS UNDER GENERAL ANESTHESIA

4. J. F. Baldwin, of Columbus, reported that, with the use of nitrous oxide in major operations, death occurred at the rate of one in one hundred cases. We must remember that death from gas poisoning comes on suddenly and without warning. Capillary bleeding is also more profuse and sometimes uncontrollable. Muscular relaxation is not obtained when nitrous oxide is given alone, and ether is generally added to produce this effect. John B. Deaver was correct, when he described this combination as ether anesthesia masquerading as a gas anesthesia, the ether doing the work and the nitrous oxide getting the credit.

Nearly every surgeon will have to admit, that during his experience, one or more untimely deaths have occurred with the use of general anesthesia. No definite accounting can be given for these accidental deaths, and it becomes questionable as to whether the anesthesia is directly or indirectly responsible. It is, therefore, important to study the remote effects of chloroform, ether, or nitrous oxide.

We know that chloroform and ether play an important rôle in the production of acidosis, but aside from this dangerous complication, there are the unpleasant after effects that are so well known to all of us.

The great danger of chloroform narcosis is self-evident, so much so that it was abandoned long ago in many of our hospitals. When death takes place, it usually occurs during the primary stage of chloroform anesthesia, yet how often do we hear physicians say that they use chloroform as a preliminary to ether anesthesia. This, in my opinion, is a great hazard to the patient and should not be practised. We must also not overlook the deleterious effects of ether and chloroform.

Nitrous oxide in recent years has gained many supporters, but gas anesthesia must be looked upon as a respiratory depressant and a dangerous anesthetic in unskilled hands.

While it is true that a longer time is consumed in operating under local anesthesia, at the same time we must keep in mind the fact that the question of safety is far more important than that of time. Many surgeons, having limited experience with infiltration, block, spinal and sacral anesthesia, are sometimes ready to abandon or condemn these methods, because they have failed to produce complete anesthesia in

some cases. They evidently do not realize that a longer time is necessary in operating; that a more refined technic must be developed when these methods are used; and that the minutest anatomical structures must be handled with the greatest amount of care.

The surgeon is therefore compelled to work more slowly, soon realizing that he must manipulate the tissues with painstaking accuracy and dexterity.

DANGERS OF GENERAL ANESTHESIA TO OLD PEOPLE

5. Labat rightfully says that the patient is frequently autointoxicated to such an extent that the normal metabolism and the oxygenation of the blood are greatly altered, thereby interfering with the essential requisites of any general anesthesia. In such cases, the advantages of regional anesthesia are obvious, since its main effects are limited to a relatively small region of the body, leaving intact the central nervous system, on the integrity of which depends the continuance of all the vital functions.

Before operating upon elderly subjects, we are in the habit of asking ourselves the following questions: First—What risk is there of anesthesia pneumonia? and second—How great is the danger of cardiac failure or kidney insufficiency? Would not the patient's chance of recovery be assured if these and other known dangers attending general narcosis could be avoided, if not altogether eliminated, through the use of a safer anesthetic? Alarming complications often occur after operations upon the aged, and we must always consider them before any particular type of anesthesia is selected. We should, therefore, choose the method least dangerous to life, and at the same time productive of the most satisfactory results.

In some parts of Austria and Germany local and regional anesthesia is now the method of choice in the performance of major surgery. So thorough has been the education in its use, that it has become a matter of routine procedure in some of the larger gynecological clinics of Vienna and various other countries.

LOCAL ANESTHESIA NOT SUITABLE IN ALL CASES

6. Finsterer of Vienna has done extensive abdominal operations in aged subjects, with entire success. In fourteen resections of the small intestine, upon patients sixty to eighty-two years of age, he had only one death, most of the patients having been previously refused operation by surgeons working only under general anesthesia.

A careful psychic study of every individual case should be made prior to operations. We admit that all cases do not lend themselves to local and regional anesthesia. The highly neurotic, excitable patient, as a rule, is not a desirable subject for this method. Those of phlegmatic type on the other hand, who have implicit confidence in the surgeon, are ideal cases for operation under these conditions.

Patients of any age on entering a hospital are likely to be apprehensive, and in a state of lowered resistance; the preparations for operation are often exhausting, and the psychic state which is reached before the operation is actually begun is often such as to greatly increase the surgeon's difficulties and actual danger to the patient. The surgeon should make it his business to reassure the patient, and to gain his confidence, to the extent of placing reliance upon the assurance that everything possible will be done for his comfort and relief. The family physician is the surgeon's greatest aid in maintaining this relation to the operative patient, and I have always found his cooperation invaluable. A timely warning of the existence of a food allergy for oatmeal, of which I was, of course, wholly ignorant—once saved me from producing a severe anaphylaxis in a recently operated patient, and on another occasion, the family doctor's knowledge of his patient's idiosyncrasy against morphine served an equally timely purpose.

STATISTICS

Since January, 1909, I have performed three hundred and twenty-six major operations under local and regional anesthesia. Of this number, one hundred were done on patients sixty years of age and over.

Number of Operations.	*Type of Operations.*	*Method of Anesthesia*
1	Carcinoma of lip (plastic)	Block
1	Thyroidectomy	Local
2	Excision of cervical glands	Local
2	Excision of carbuncle	Block
1	Excision of axillary glands	Local
5	Thoracotomy	3 Paravertebral 2 Local
2	Cholecystostomy	Local
1	Cholecystectomy	Local
1	Gastroenterostomy (carcinoma of stomach)	Spinal and Local
2	Appendectomy	Local
3	Intestinal obstruction	Local
3	Colostomy	Local
2	Sigmoidectomy	1 Spinal 1 local
1	Exploratory laparotomy (carcinoma of stomach with metastasis in liver)	Spinal and Local
2	Umbilical hernia	Block and local
7	Umbilical hernia (strangulated)	Block and local
1	Umbilical hernia (strangulated resection of small gut)	Block and local
2	Umbilical hernia (strangulated resection of omentum)	Block and local
4	Ventral hernia (strangulated)	Block and local
3	Inguinal hernia	Block and local
13	Inguinal hernia (strangulated)	Block and local
1	Inguinal hernia (strangulated resection of small gut)	Block and local
4	Inguinal hernia (strangulated resection of omentum)	Block and local
2	Femoral hernia	Local
1	Perinephritic abscess	Local and paravertebral
1	Nephrotomy	Paravertebral
1	Nephrectomy	Paravertebral
9	Suprapubic cystotomy	Local
8	Suprapubic prostatectomy	3 Sacral and local—5 Sacral, parasacral and local
2	Excision testicle and epididymis	Block and local
2	Excision inguinal glands	Block and local
1	Hysterectomy	Spinal
1	Salpingooophorectomy	Spinal
1	Amputation of fingers	Block
1	Osteomyelitis of radius	Block and local
1	Osteomyelitis of femur	Block and local
1	Amputation of foot (diabetic gangrene)	Block
2	Amputation of leg (thromboangitis obliterans)	Spinal
2	Amputation above knee (diabetic gangrene)	1 Spinal block
100		

This series of one hundred operative cases represents a large field of major surgery. Interventions upon the head, neck, chest, abdomen, pelvis and extremities were successfully performed with local and regional anesthesia. The age of our patients ranged between sixty and ninety-four years. The average age was sixty-eight years. The cases were about equally divided between the two sexes; fifty-four being males and forty-six females. The females proved more desirable subjects for this method of anesthesia than did the male patients. Race played an important rôle in the suitability of our cases for local anesthesia. The phlegmatic patients, as a rule, were more desirable for this method of operation

than were the socalled neurotic types, such as the Italian, Jewish and Negro patients.

In our series the anesthetic of choice was novocaine, although apothosine, and quinine and urea hydrochloride were administered in a limited number of cases (7). Quinine and urea hydrochloride anesthesia may last for an indefinite period. The prolonged anesthesia is explained by the infiltration of the nerves and tissues with a granular fibrin, and the period of anesthesia depends entirely on how soon this fibrin is absorbed.

Though the latter substitute was used during the late war, when novocaine was not so plentiful—novocaine is, in my opinion, the most reliable and dependable local anesthetic. The solution should be freshly prepared for each operation. The percentages used were as follows:

For infiltrating the immediate line of incision or around the operative area, novocaine solution one half of one per cent., with or without adrenalin. For paravertebral and parasacral conduction anesthesia, one per cent. novocaine solution, with or without adrenalin.

For spinal anesthesia .01 gm. of novocaine for every fifteen pounds of body weight of the patient. In other words, a patient weighing one hundred and fifty pounds would get .10 gm. or one grain and a half of novocaine intraspinously without the addition of adrenalin. The powdered novocaine is introduced in the syringe and about ten c. c. of spinal fluid is withdrawn. The novocaine, being readily soluble in this fluid, is reinjected intraspinously. Anesthesia is produced almost instantaneously. No adrenalin is added.

For sacral anesthesia twenty-five to thirty cubic centimetres of a two per cent. solution of novocaine are injected into the sacral canal and not into the spinal canal. With this process, the sacral plexus is bathed in the anesthetic fluid. All sensory impulses are blocked along the areas supplied by the sacral plexus. These areas are the lower rectum, anus, perineum, labia minora and majora, clitoris, vagina, cervix, bladder, penis, prostate and ischiorectal region. Anesthesia is produced in fifteen to thirty minutes. If parasacral anesthesia is combined with this method, the anesthetic effect is more prompt.

The selection of local anesthesia, whether infiltration, block, paravertebral, spinal, sacral or parasacral, depends more or less on the individual case.

Of the one hundred patients operated on, there were six deaths. Fifteen patients were practically moribund and many of the remaining cases showed evidences of one or more of the following complications before operation: bronchitis, emphysema, pneumonia, mitral and aortic valvular disease, myocarditis, advanced arteriosclerosis, nephritis, cirrhosis, peritonitis, diabetes, etc. This death toll, in my opinion, is not high, when we consider that many of our patients were poor surgical risks for general anesthesia and not altogether suitable for local and regional anesthesia. In some instances it became necessary to perform more than one operation at one sitting. The deaths were as follows:

CASE REPORTS

Case I.—An alcoholic gentleman of sixty-five was admitted to the hospital in desperate condition. An operation for strangulated inguinal hernia was performed and he died three days later of delirium tremens.

Case II.—A woman, eighty-two, with cardiac decompensation, was operated on for cholelithiasis and on the tenth day she died of hypostatic pneumonia and cardiac failure.

Case III.—A diabetic, seventy-eight, with gangrene of the foot. This woman had an amputation done at the midthigh. She died on the twenty-first day after operation in diabetic coma.

Case IV.—A woman, seventy-four, under paravertebral anesthesia was operated on for perinephritic abscess. She was in poor condition before operation and died of uremia twelve days later.

Case V.—A man, sixty-two, had a gastroenterostomy done for carcinoma of the stomach. He vomited continuously for a period of ten days prior to admission to the hospital. Patient died of inanition five days after operation.

Case VI.—Carcinoma of the prostate with nephritis. This man, seventy-five, also had a pronounced aortic lesion. Under sacral anesthesia an enlarged prostate was removed and five days later he died of uremia with cardiac failure.

ADVANTAGES OF LOCAL AND REGIONAL ANESTHESIA

After all, local and regional anesthesia have many advantages over inhalation anesthesia in operations upon the aged.

Cases that were formerly considered inoperable and hopeless with the use of general narcosis are now given a fighting chance with the newer methods of local and regional anesthesia. Vomiting rarely occurs, there is little complaint of thirst, and catheterization is seldom necessary. Shock is greatly diminished, because the tissues are handled with greater care. Hemorrhage is reduced to a minimum because closer attention is given to the minutest bleeding vessels.

Postoperative pain is diminished and sometimes altogether absent. The serious postoperative complications, such as pneumonia, cardiac failure, nephritis and acidosis are rarely encountered. Nourishment is given shortly after operation, the convalescing period is shortened, and the patient, satisfied with the treatment and results, frequently recommends this method of anesthesia to others.

Adenoids in Infancy: The Importance of Early Treatment

WILLIAM WESLEY CARTER, M.D., F.A.C.S.

New York

Though the subject of adenoids is one which may well be considered trite, and which without forced deliberation, I will admit, seems to have been adequately discussed from every point of view, yet I am satisfied that the importance of adenoids in infancy and early childhood is so great that further discussion is not amiss, especially as there exists considerable diversity of opinion among the family doctors as to how these cases should be treated, and as the family doctor is the first to note the condition, it is well that he should be acquainted with the views of the rhinologist upon the subject. No obstetrician, pediatrist or general practitioner is unfamiliar with the symptoms of the adenoid baby.

Nature ordained that the infant should breathe through its nose, and the moment this instinctive reflex is interfered with there is trouble, for the child does not know how to breathe through its mouth and it must suffer continuously, almost to the point of suffocation, until the mouth breathing habit is established; once this vicious habit has been formed and the afferent and efferent impulses to and from the nerve centre have been established in perverted channels, the foundation is laid for the train of symptoms and complications which result from nasopharyngeal obstruction, and to those malformations of the hard palate, the upper jaw, the nose and the face familiarly known as the adenoid facies.

If it is possible to prevent these dire results of nasal obstruction, no apology is needed for emphatic and repeated urging of all to heed at once and treat these cases radically when the obstruction has persisted for a time sufficient to convince us that it is of a more permanent nature than that caused by turgescence of the nasopharyngeal tissues.

The nasopharynx of the suckling infant is small and an incredibly small adenoid growth will cause obstruction, especially if it is engorged with blood. At birth the infant's nasopharynx is only one quarter of an inch high and one third of an inch wide; by the end of the first year this space has doubled in size. It will be realized at once, therefore, that during the first six months of life the postnasal space is relatively smaller than at any other age, and anything tending further to restrict this small space, whether it be an adenoid or congestion of the mucous membrane, is far more effective in obstructing nasal respiration at this age than at any other time of life, and a small adenoid may call for operative consideration which later on would produce no symptoms and could safely be ignored.

During the early weeks of life the most common symptoms of adenoids are difficulty in nursing continuously and snuffles. The latter may be attended by a mucopurulent secretion which sometimes excoriates the nostrils and upper lip; this condition has been mistaken for congenital syphilis. I have seen children being treated for syphilis who have recovered promptly after the removal of a small adenoid. Great care should be exercised in making a diagnosis in the case of infants having the socalled classical symptoms of congenital syphilis; embarrassing mistakes have been made. I know of one case where a suit for heavy damages was narrowly averted because of the mistake in diagnosis. The patient was the only child of a distinguished artist. The child certainly did have the snuffles with excoriations and the general appearance of a congenital syphilitic, but it was Wassermann negative. She promptly recovered after I had removed a small adenoid and a proper modification of the milk had been effected. A nonsyphilitic child affected with snuffles may safely be diagnosed as having adenoids, and other things being equal, an operation will be wisely advised. There may be little or no obstruction, but the adenoid is there and it is producing irritation and should be removed.

Obstructing adenoids cause mouth breathing, making it impossible for the nursing child to take either the breast or the nursing bottle satisfactorily. If the obstruction is continued long enough the well-known adenoid facies is the result, and this term is used here to cover the complications involving the mentality and hearing of the patient as well as the resulting physical deformity which is familiar to all observers.

In operating, no anesthetic is administered. The child is wrapped in a sheet, as in doing an intubation, and is held by an assistant in his arms, the head of the child resting on his right shoulder, and the left

hand of the assistant being placed on the forehead of the patient, holds the head in position. I use a very small Gottstein curette and make only one sweep. I make no attempt to remove the entire mass of adenoids. In fact I try not to do so, for I believe that lymphoid tissue, within normal limits, should be left undisturbed, and that operative measures should be considered only when this tissue is diseased or present in sufficient volume to produce obstruction to nasal respiration or interference with the function of the Eustachian tubes.

CONCLUSION

In conclusion I will say that the advantages to be gained by this simple operation are so great that one is amply justified in advising it when symptoms referable to adenoids are present. The operation should not be postponed with the expectation that the infant will overcome the difficulty as it grows older and that there will be no disagreeable sequelæ; the chances are against such a happy outcome.

The Conservation of Hearing in the Suppurative Middle Ear Diseases of Childhood*

RALPH ALMOUR, M.D.
New York

The factors which are capable of causing disturbances of the hearing in young children are numerous. In this paper, however, I will limit myself to a discussion of the conservation of hearing in the suppurative middle ear diseases of childhood. It is in these conditions that much can be accomplished by preventive measures and rational therapy.

The acute diseases of childhood often give rise to aural complications of a suppurative nature. In many instances, a paracentesis of the drum is required to afford egress to the pent up pus. Where this becomes necessary, the incision should be in the lower and posterior quadrant of the drum. Such an incision properly made will remain open as long as there is pus in the middle ear. The pressure of the pus and the contraction of the radiating fibres of the drum will not permit the opening to heal as long as there is need for its remaining patent. When the disease subsides, this opening will be bridged over by connective tissue and eventually closed. This then becomes the seat of a scar which, in the great majority of instances, scarcely interferes with either the function of the drum or the acuity of hearing.

To make several incisions in the drum or to make repeated incisions in the hope of warding off graver consequences is a procedure to be deplored. Such methods only serve to destroy more of the drum substance and lessen its elasticity, with a consequent disturbance in the conduction apparatus. Those who employ them do so to afford more room for drainage and so prevent the production of a mastoiditis. This theory is not supported, however, when one considers the pathogenesis of a mastoiditis produced by contiguity of tissue. With a timely incision properly performed, adequate drainage of the pus in the tympanum is obtained. When signs of mastoiditis supervene after such an incision has been made, one cannot then consider that the lesion in the mastoid was caused by the damming back of pus. Such a lesion is caused by the spread of infection through the contiguity of tissue and subsequent incisions in the drum are useless in attempting to ward off a disease which has already developed. A mastoiditis is present. Whether it will develop into a condition requiring surgery is not dependent upon the drainage afforded through openings in the drum but upon the ability of Nature to combat the infection successfully.

In the treatment of acute otitis, many have recently begun to advocate the use of suction as a preventive of mastoiditis. It is hoped, by this procedure, to suck the pus forcibly from within the mastoid cells through the antrum and aditus into the tympanum. To me, this is a valueless as well as a dangerous procedure. All acute middle ear suppurations are attended by a reaction in the mastoid cells. This is clinically evinced by pain and tenderness over the mastoid process and radiographically by a clouding, but not a destruction, of the mastoid cells. To apply suction in such a case cannot be termed a preventive measure. On the contrary, suction increases the edema of the parts, distorts the drum by making it edematous and angry looking, prevents the closure of the opening in it which would have healed as soon as the discharge diminished, and lastly, exerts undue traction on the ossicular chain. The tympanic cavity is therefore expected to repair not only the damages of the suppuration but also the harm done by the suction, and the period of convalescence is prolonged. Such cases when tested show a decided diminution in the hearing in the affected ear.

Where a surgical mastoiditis is present, suction cannot cause an abatement of the disease. When we consider the mechanics of the procedure this at once becomes clear. The aditus ad antrum is situated at the upper posterior portion of the tympanic cavity in a space conspicuous for its numerous reduplicated folds of mucous membrane. Negative pressure of any degree would cause a dilatation of the capillaries in these parts with a consequent engorgement and edema of the mucous folds. The mucous lining of the aditus likewise swells and there is thus created an obstruction to the free passage of pus through the antral opening. The use of suction, therefore, defeats the purpose for which it is employed. I have seen several cases of surgical mastoiditis which were treated in this manner and which later came to oper-

*From the Otolaryngological Department of Beth Israel Hospital, New York. Read before the Eastern Medical Society, October 10, 1924.

ation. All of the patients so treated presented broken down mastoid cells filled with debris, and in addition had either a perisinal or epidural abscess. One patient had a sinus thrombosis and another a brain abscess which eventually ruptured and produced a fatal meningitis.

There are many patients with mastoiditis presenting all the indications for surgical intervention, which will suddenly apparently subside, the temperature return to normal, and the pain disappear, but the discharge from the middle ear will persist. Those who employ suction attribute this recession to their success in drawing off the pus from the mastoid. In these cases, though the patients then are relieved of an imminent surgical condition, they are confronted with a chronic suppuration of the middle ear due to a chronic mastoiditis. The pus will continue to pour out with or without the aid of suction until the mastoid process stops suppurating. In other words, Nature operates upon the mastoid and the pus is afforded egress through the middle ear. In these cases, the drum becomes the seat of a permanent deficiency, the tympanic mucosa is destroyed in spots and replaced by scar tissue, and eventually, if the process is permitted to continue, adhesive bands make their appearance between the ossicles and the neighboring structures. The result is a marked diminution in hearing.

Let us return for a moment to the question of the surgical mastoid produced by contiguity and which has been termed the coalescent mastoiditis by Kopetzky. In the majority of cases, this type presents symptoms so alarming to the parents of the child that they do not hesitate in permitting an operation to be performed for the relief of the condition. In some cases, however, especially in the socalled painless type of mastoiditis, or in the cases wherein the more sensational symptoms have disappeared and only the aural discharge persists, the parents can see no reason for the performance of an operation. The family physician likewise sees that all danger is past for the present and frequently proceeds to treat the discharge in the hope of causing it to cease entirely. As I have pointed out, this discharge has its source in the mastoid process and will not stop until all the remains of the suppuration have been removed therefrom. One alternative suggests itself. On the one hand, while the patient may continue in apparent safety, there is a suppurating discharge present which is constantly destroying tissue both in the mastoid and in the middle ear, and which, while it may eventually cease entirely, will leave the patient with markedly affected hearing. On the other hand, if the simple mastoid operation is performed, the disease is removed *en masse,* thus permitting the middle ear to return to normal and the greatest amount of hearing is thereby preserved. Obviously, the latter is the course to pursue, and it is the duty of the general practitioner in his rôle as counsellor to impress upon such patients that the mastoid operation, performed in these cases as a prophylactic measure, presents far less danger than the presence of a suppuration within the mastoid which is destroying the hearing and which may threaten the endocranium.

In the cases of chronic suppuration in children, wherein hearing has already been markedly affected, the general practitioner is often at a loss to determine what to do to stop both the discharge and the loss of hearing. In those cases wherein the discharge is due to a chronic mastoiditis with bone necrosis, it was formerly the custom to perform a radical mastoid operation to cure the lesion and stop the discharge. The element of hearing was not considered, and, while the discharge stopped, these patients had complete loss of useful hearing in the operated ear. The children were consequently handicapped in school and had great difficulty in obtaining an education. The radical operation is at present rarely performed on children. Where the case of bone necrosis presents signs which point toward a possible danger of intracranial invasion, it is sufficient to perform a simple mastoid operation. This removes the disease in the mastoid process and, by keeping a permanent opening leading down to the antrum, the discharge from the tympanic cavity is afforded drainage through the middle ear and through the retroauricular opening. All danger of intracranial invasion is thus prevented and the hearing is not further reduced by operative procedures in the middle ear. These patients are thus given the benefit of using whatever hearing remains in the affected ear and at the same time are relieved of the danger that the disease presents to life.

Where the discharge is due to what is termed a chronic suppuration of the tympanic mucosa, the method of procedure is different. Here the mastoid cavity is not the seat of the disease and consequently need not be considered in the means used to conserve the hearing. These cases of chronic suppuration of the tympanic mucosa are caused by repeated infections from the respiratory passages and by a lowering of the patient's resistance. They all have defects in the drum, centrally located, and present a discharge which is intermittent in character. The patients may have freedom from the discharge for years, and then, with a lowering of the vitality or a nasal catarrh, the discharge will start anew. In the conservation of the hearing in these cases our attention must be directed toward maintaining the general health of the patient and correcting any disturbances in the respiratory passages which may predispose to another attack of otitis. Obstructions such as excess adenoid tissue, occlusive septal deflections and polypi and suppurative foci such as infected tonsils, sinusitis and poor teeth, these are the elements to be corrected before one can hope to stop the aural discharge and so conserve the hearing. Local treatment to the ear merely allays the individual attack. Attention to these details prevents further attacks.

SUMMARY

1. A timely incision in the drum, adequately performed, meets the indications presented by a bulging drum due to an acute purulent otitis media. To make multiple incisions or to make repeated incisions in the drum tends to destroy the function of the membrana tympani and leads to a subsequent loss in the acuity of hearing.

2. The use of suction in the treatment of acute middle ear diseases produces no result other than an

irreparable loss of tissue in the middle ear and a consequent diminution in hearing.

3. An aural discharge of long standing destroys tissue in the middle ear and mastoid process. Cases presenting such a lesion should be adequately treated before too great a loss in hearing has occurred.

4. The performance of a simple mastoid operation is to be preferred to expectant treatment in acute suppurative diseases of the mastoid process which have apparently subsided, but which present a persistent, profuse aural discharge.

51 West Seventy-third Street.

Acute Intussusception in Infants

ROBERT L. GIBBON, M.D.

Charlotte, N. C.

During the past three and a half years I have operated in a consecutive series of eleven cases of acute intussusception in infants with one death, or less than ten per cent. mortality. Stewart gives the average mortality in cases where reduction is easy thirty to forty per cent., but when reduction is impossible ninety per cent.; Bolling, from the service of W. A. Downes, in a series of fifty cases has a mortality of thirty per cent.; Clubbe in a series of 270 cases, twenty per cent.; Hipsley in fifty-one operations eight per cent. It is generally recognized at the present day that the factor of most importance is early diagnosis, and the only treatment is laparotomy and reduction of the intussusception. As a general rule the most favorable cases are those in which the interval between the onset of the symptoms and the time of operation is shortest. However, it will be found when a large number of cases are compared, and is even evident in our small series of eleven cases, that there is a striking variance in the rate with which the condition progresses in individual cases. In other words, what is considered an early diagnosis, from the viewpoint of time, in one case is late for another. Resection may be necessary because of tremendous swelling of the bowel and irreducibility in one case which is early from the viewpoint of duration of symptoms, while in another reduction may be easily accomplished when the duration of the symptoms is longer. The greatest difference is therefore manifested in the rate with which the condition progresses.

An analysis of the eleven cases herein reported brings out certain interesting features. There were three females and eight males. All were breast fed, healthy infants. Only one was above twelve months of age. In each case the onset was more or less abrupt with the usual symptoms. Resection was done in two cases with one recovery. The patient who recovered was a five months baby, operated on twenty-eight and a half hours after onset of symptoms. The symptoms in this case had developed rapidly and at operation there was so much swelling at the apex of the intussusception that reduction could not be accomplished without ripping the bowel wall. The cecum and part of the ascending colon were removed, and the terminal ileum united to the hepatic flexure by a lateral anastomosis. The bowels moved the day following operation. Recovery was rapid. In another patient eight months of age, duration of symptoms from the onset to the time of operation was seventy-two hours, or three days, the apex of the intussusception protruded from the rectum. At operation reduction was easy and rapidly accomplished. The convalescence was calm. The fatal case was an enteric intussusception in a male baby three months of age, of forty-eight hours' duration, in which resection of the small intestine was done for gangrene. The patient died shortly after the operation. The earliest patient operated on was ten to twelve hours after onset of symptoms. In two cases where the diagnosis was uncertain because it was not possible to feel a mass at first, fluoroscopic examination after a barium enema was helpful in arriving at a diagnosis.

Considerable differences also are observed in the type of convalescence. In some the convalescence was uneventful and rapid, the patient leaving the hospital six to seven days following the operation. In other cases it was of extreme violence, temperature running for days from 103° to as high as 106°. In one case reported, following the operation, there was a temperature of 106.5°.

ETIOLOGY

In regard to the etiology of this interesting condition, the actual cause has never been decided. It is generally known that in infants there is a much greater mobility of the lower ileum, cecum and ascending colon due to an unusually long mesentery. With a bowel, which is more irritable and in which muscular action is not so well coordinated, it is possible that these factors in infants predispose to acute intussusception. Injudicious feeding is stressed by many authors, other authors feel that active purgation in infants has a tendency to produce the condition. In the eleven cases reported, only two gave a positive history of any gastrointestinal disturbances prior to the onset of symptoms. This disturbance was manifested only by a mild diarrhea. In none of the cases were purgatives given prior to the onset of the symptoms. Every baby was breast fed and well nourished.

Perrin and Lindsay have come to the conclusion that the determining factor in the causation of intussusception is the production of the equivalent of a foreign body within the intestine. The foreign body is provided by the swelling of the preexisting lymphoid tissue within the intestinal wall. The

factor which produces this swelling is some gastro-intestinal disturbance. This seems especially likely when it is remembered that the distribution of the lymphoid tissue in this part of the alimentary canal in infants is unusually abundant. It is common for all operators in these cases to find greatly enlarged lymphatic glands in the mesentery about the ileocecal region.

PATHOLOGY

The pathology of acute intussusception in infants depends upon the disturbance in the blood supply of the invaginated loop of gut. The invaginated bowel as it passes into the enveloping gut or sheath drags its corresponding part of the mesentery with it. At the neck of the intussusception, the mesentery becomes constricted, and the free flow of blood through the vessels impeded. The degree of this constriction at the neck of the intussusception becomes therefore an important item, not only in the development and nature of the pathological changes in any given case, but also in the clinical features of the same case. At first, in the majority of the cases, this constriction is not tight. It possibly is only sufficient to obstruct the venous return in the mesentery. As a result of this the veins dilate, and distend. Progressive engorgement of these at last causes the walls of the terminal venules in the intestine to give way, and the intestinal wall becomes ecchymotic and infiltrated with extravasated blood. The mucosa of the intestine becomes intensely congested, and soon begins to pour blood and mucus into the lumen, and this appears in the stools. As the engorgement and swelling goes on in the intestinal walls, the constriction at the neck of the intussusception grows tighter and more binding with a still greater impediment to the circulation.

Finally, the arterial circulation supplying the intussuscepted loop of intestine is obstructed, and gangrene quickly results. When a tight constriction of the mesentery develops suddenly causing a very quick alternation in the circulation, the pathological changes in the gut develop more rapidly,—the intestine becomes more markedly infiltrated, swollen and edematous, making reduction more difficult and even impossible, although the patient may be seen early. Gangrene naturally develops sooner and the case moves on more speedily to a fatal termination. The severity of the symptoms at the onset and the rate of progress in the development of these, depend therefore greatly on the degree of the constriction at the neck, and the extent to which the circulation is obstructed. Moorhead calls attention to cases in which the constriction may not be so severe, but in which a low form of inflammation sets in, the walls of the gut become thickened, adhesions develop between the peritoneal surfaces, sometimes at the neck only, but more frequently wherever they are in contact, and if the patient lives the whole of the intussuscepted part may slough off. When the constriction is lax there may be no change in the intestinal wall.

Complete obstruction of the intestine is rare. Normal bowel movements do occur after the onset of symptoms, and gas may be passed readily during the later stages. This is no doubt the reason that so few of the cases show any abdominal distention. With the increasing edema and swelling of the bowel walls, and particularly the apex, complete obstruction sometimes develops in the late cases, with distention of the abdomen, fecal vomiting, profound toxemia, and other symptoms. To summarize, however, it is evident that in the great majority of the cases the severity of the symptoms depends more on the degree of the interference with the circulation than upon the obstruction of the bowel.

The ileocecal region is the most usual site of occurrence. The frequency with which ileocecal intussusception occurs is due to some extent to the difference in size between the two parts, and to the fixed position of the cecum. The very close analogy between the sphincterlike ileocecal valve and the sphincter of the rectum, and between the invagination that takes place at the one, and the prolapse that occurs with equal frequency, especially in children, at the other, has been noted by Moorhead. "Ileocecal tenesmus probably sets in whenever there is any violent catarrh or abnormal irritability of the intestine, just as anal tenesmus occurs in similar conditions in the rectum; and the repeated forcible peristalsis, driving down on the firmly closed ileocecal valve, causes intussusception in the one case, just as it causes prolapse of the rectum in the other. When the invagination has commenced, the contact of the swollen and congested apex, stimulating the walls of the intestine below, tends to make it increase indefinitely."

The classification of Clubbe is usually accepted for distinguishing the anatomical forms of intussusceptions: First, the ileocecal variety, includes forty-four per cent. of the cases, and is the form in which the ileocecal valve or the head of the cecum forms the apex, the intussusception growing at the expense of the colon. Owing to the great mobility of the ileum, a large portion of the bowel may be invaginated, passing through the colon and rectum and appearing at the anus. Second, the enteric, which includes thirty per cent. of the cases, and in which the small intestine alone is involved. Third, the colic form, which may occur at any point of the colon or rectum, but owing to the fixity of this portion of the bowel, is limited in extent. The colic variety includes about eighteen per cent.. of the cases. Fourth, the enterocolic type includes two forms. In one the intussusception, beginning in the ileum, near the valve, goes through the valve, and increases at the expense of the cecum and colon. In the other, the intussusception begins in the ileum, but when it reaches the valve, pushes the valve before it, and increases at the expense of the cecum and colon. In this type, when the cecum is unfolded, the enteric intussusception is seen to emerge and when the cecum is completely unfolded it is found to be empty. Enterocolic intussusceptions are really double, the socalled compound intussusceptions of some authors. Richard Bolling and Culberth Wallace are of the opinion that these forms are more common than generally conceded—eight per cent. of cases.

Intussusceptions rarely occur during an attack of ileocolitis. While this is not usual it is frequent enough to be kept in mind.

DIAGNOSIS

Perhaps the single, most essential phase of acute intussusception in infants is the question of early

diagnosis. There is no other surgical condition which demands more promptitude and certitude of diagnosis, if the life of the infant is to be saved. The condition is always grave, and must be dealt with in a decisive manner. In the late, unrecognized, neglected cases the patients will die regardless of the treatment in most instances. The whole problem of intussusception practically resolves itself into one of early and prompt diagnosis followed by proper treatment. It is a fact also which is gradually becoming more evident that the diagnosis is not a difficult one, even in the early cases, if the condition is suspected and some care is exercised. It is my experience that

The clinical picture is one of remarkable vividness. A healthy, growing, thriving, breast fed infant, three to five months of age, usually a male, suddenly cries out, or begins to scream and draws himself together as if in great pain. He grows pale, and possibly may break into a moderate perspiration. After a variable time the baby grows calm again and seems to be comfortable, only to be seized shortly with another similar attack. Sooner or later vomiting occurs—usually at first the contents of the stomach. He vomits every feeding after the onset of the symptoms. There may be one or more normal bowel movements after the beginning of the symptoms.

ANALYSIS OF CASES

Name	*Age*	*Sex*	*Symptoms*	*Duration*	*Physical Signs*	*Operation*	*Result*	*Type*
1. H.H.	7 Mos.	M	Sudden onset with pain, bloody stools and rather late vomiting.	46 hrs.	Slight elevation of temperature and pulse. Some stupor. Mass extending across centre of abdomen.	Nov. 17, 1921. Laparotomy. Easy reduction.	Recovery. Rapid convalescence.	Ileocecal
2. C.L.	10½ Mos.	M	Onset with colic, one normal b.m., followed by blood and mucus later, symptoms as a whole mild. No shock.	18 hrs.	Bright and alert on adm. Moderate elevation of pulse and temperature. Mass to right and below umbilicus. Easy to feel.	April 3, 1924. Laparotomy. Reduction, very marked edema, some difficulty in reducing.	Recovery. Convalescence very quiet.	Ileocecal
3. R.L.	8 Mos.	M	Onset sudden, colic, vomiting, no blood and mucus by stool.	10 to 12 hrs.	Restless, slightly elevated pulse and temperature. Easily palpable mass in upper right abdomen.	May 10, 1924. Laparotomy, reduction easily and quickly carried out.	Recovery. Quiet convalescence.	Ileocecal
4. A.S.	6 Mos.	M	Onset with colic, vomiting, shock and fever. No blood or mucus by stool.	17 hrs.	Restless, pale, elevated pulse and temperature, very indefinite mass in upper right abdomen. Barium enema—obstruction at hepatic flexure.	July 6, 1924. Laparotomy. Reduction. Mass high up beneath liver. Easily reduced.	Recovery. Rapid convalescence.	Ileocecal
5. W.S.	3 Mos.	M	Colic, vomiting, blood and mucus by bowel.	48 hrs.	Shock, fever, rapid pulse, convulsions, mass in lower abdomen.	May 15, 1923. Laparotomy. Resection. Gangrene of intestine.	Death.	Enteric
6. W.R.	8 Mos.	M	Vomiting, blood and mucus by bowel. Marked toxemia, straining.	72 hrs.	Marked shock, subnormal temperature, rapid pulse. Mass in lower abdomen. Apex protruded from rectum.	May 27, 1923. Laparotomy. Reduction.	Recovery. Calm convalescence.	Entero-colic
7 R.P.	5 Mos.	M	Abrupt onset with pain, shock, vomiting, blood and mucus by bowel.	28½ hrs.	Mass to left of umbilicus, toxic stupor, pallor, rapid pulse, high temperature.	Oct. 11, 1923. Resection right half of colon. Irreducible.	Recovery. Convalescence complicated by wound infection.	Ileocecal
8 C.F.	6 Mos.	F	Sudden onset with pain, pallor, and perspiration, vomiting, blood and mucus by stools.	36 to 40 hrs.	Mass in upper right abdomen. Elevated pulse and temperature.	Nov. 5, 1922. Laparotomy. Reduction.	Recovery. Quiet convalescence.	Ileocecal
9. K.S.	14 Mos.	M	Onset sudden with colic, vomiting, mucus and blood by stools.	24 to 36 hrs.	Elevated pulse and temperature, tumor mass in lower abdomen.	July 22, 1921 Laparotomy. Difficult reduction.	Recovery. Stormy convalescence complicated by pneumonia, temperature range 101 to 105 for one week.	Ileocecal
10. H.P.	3 Mos.	F	Onset without much pain, but with vomiting, blood and mucus by stools. Only pain manifested by grunting.	43 hrs.	Elevated pulse, and temperature, mass in left flank.	July 2, 1923. Laparotomy. Easy reduction.	Recovery. Comparatively quiet convalescence.	Ileocecal
11. M.C.	3 Mos.	F	Onset sudden with vomiting and pain, passage of blood and mucus by stools.	28 hrs.	General appearance on adm. good. Temperature and pulse elevated. No mass felt. Barium enema showed obstruction in hepatic flexure.	Aug. 9, 1922. Laparotomy. Easy and quick reduction.	Recovery. Extremely stormy convalescence, high temperature, rapid pulse, restlessness, convulsions, with great intoxication.	Ileocecal

a few hours' close observation will usually clear up a diagnosis that at first seemed obscure. An infant suspected of having an intussusception should be at once placed in a hospital where he can be kept under satisfactory scrutiny. There is an exception to the usual simplicity of diagnosis and that is the type of case in which intussusception comes on and is superimposed upon an ileocolitis. The diagnosis then of course is extremely difficult. However, in most instances I believe the diagnosis can be made, if not by one means, then by another, and I have not yet encountered the necessity of doing an exploratory operation on these little infants.

The absence of intestinal obstruction, therefore, never militates against the diagnosis of intussusception. Sooner or later stools consisting largely or solely of blood and mucus are passed. Associated with these passages there is a great deal of straining and tenesmus observed in the patient. In the early stages the baby may look well, and be playful between the paroxysms of pain, vomiting, and other symptoms, but as time goes on he begins to appear more toxic. The temperature and pulse mount, the baby grows dull and listless, becomes extremely pale, the vomiting is almost continuous, and nothing comes from the bowel, except blood and mucus. With

the development of complete bowel obstruction, the abdomen becomes distended, fecal vomiting ensues, and death from toxemia quickly follows.

Such are the symptoms. Of course, they vary in intensity in different cases, as already brought out in the discussion of the pathology. There are cases reported in the literature and occurring in my own experience, in which the symptom of pain was greatly masked, possibly indicated only by a little grunting or straining of the patient, but in which the repeated appearance of blood and mucus in the stools was the first symptom to be noted by the parents. Discharge of blood and mucus may be entirely absent, although this is the most constant of the symptoms.

DIAGNOSIS

The diagnosis can in the majority of the cases be made on the history and physical examination. When a healthy baby becomes ill with striking abruptness, suffers paroxysms of pain, associated with more or less shock, vomiting, and the passage of blood and mucus by bowel, and when on examination an elongated, rounded mass can be felt in the abdomen, the evidence is sufficient to reveal the condition. The most valuable item, besides the pallor, temperature, and pulse elevation, to be noticed on physical examination is this mass in the abdomen, and it is really the major part of the diagnosis. The mass in the early cases is on the right side, or just above the umbilicus, and sometimes a little below it. Later it is on the left side and in the pelvis. In some instances it is extremely easy to feel, is almost visible, in others best felt by the combined rectoabdominal method—in some cases palpable only with the infant under an anesthesia, and in others it is almost impossible to feel. The situations in which palpability is difficult are when the mass is located high up beneath the liver on the right, or when for some reason the mass closely hugs the posterior abdomen and is overlayed by all of the small intestines. Close observation, with examinations at frequent intervals, or under an anesthesia, may make it possible to demonstrate the mass.

There still will remain cases which are doubtful, cases in which the sensation of feeling a mass is extremely uncertain, at the most. What is to be done with cases of this type? My practice has been to administer a barium enema, and study the colon under the fluoroscope. Nothing but satisfactory results have been met with in the employment of this agency. In one early case, the patient was not extremely sick, and a mass could not be perfectly made out, the intussusception was demonstrated at the hepatic flexure. At operation the mass was found high up beneath the liver. In another case with only the symptom of passing blood and mucus by stools, also an early case, fluoroscopic examination after an enema was helpful in reaching a diagnosis. In a third case, presenting all of the classical symptoms, without a palpable mass, fluoroscopic observation showed the colon to be normal. Operation was delayed, the infant kept under observation, improved rapidly and finally recovered. Of course if the intussusception is enteric this method of examination is of no value; but as enteric intussusceptions account for only thirty per cent. of the cases a clear colon on fluoroscopic examination argues against intussusception in at least seventy per cent. of all cases.

In regard to the question of spontaneous reduction, it is evidently a fact that such a thing does occur. It is quite possible that slight degrees of intussusception undergo spontaneous reduction more commonly than is usually imagined, the cases presenting the usual symptoms of onset but in a short while completely recovering. Andrew Fullerton, of Belfast, reported the history of an unmistakable case of spontaneous reduction. This case was a male child, aged three months, with the usual onset and symptoms of acute intussusception, and a palpable mass in the right side of the abdomen. The author remarked that under the palpating finger the mass was felt to grow smaller and finally disappear. In spite of this fact, the diagnosis of intussusception was made and immediately an operation performed. The pathological findings in the cecum and terminal two inches of the small intestine were characteristic of an intussuscepted bowel after reduction, the walls being very edematous and ecchymosed.

TREATMENT

There are various reports of cases in which reduction is said to have occurred after the use of enemas and the installation of other agents in to the rectum. Immediate laparotomy, however, for purposes of reduction of the intussusception under the guidance of the hand and eye is the recognized means of treating these cases today. As a general rule, the reduction in early cases is not difficult and can often be quickly performed. However, resection is sometimes necessary even in the early cases because of the tremendous swelling which has developed in the apex and does not permit reduction without splitting the bowel wall. Of course where gangrene has occurred resection and anastomosis is the only outcome. Resection naturally carries a high mortality rate. In reducing the intussusception only sufficient amount is reduced in the abdomen to permit the mass to be brought to the outside, where the reduction is completed. Many English surgeons make a practice of removing the appendix at this time, but this seems to add something to the risk of the operation without any distinct advantage.

Doses for Children

A. D. BUSH, M.D.
Emory University, Georgia

Multiply the age of the child by five; the resulting product will be the correct percentage of the adult dose suitable for a child of that age.

Suppose the child is five years old, and the physician wishes to administer a medicine of which the average adult dose is eight grains (or one half gram). First multiply the age of the child by five, and the result, twenty-five, equals the right percentage (twenty-five per cent.) which the child of five should take of eight grains; twenty-five per cent. (or one fourth) of eight equals two; therefore the child of five should take two grains when the average adult dose is eight grains.

Compare this with the cumbersome fraction of Young's rule. Young's rule calls for that fraction of the adult dose formed by the age of the child for a numerator and the age plus twelve for a denominator. In the example given, five, the age of the child becomes the numerator and five plus twelve, or seventeen, becomes the denominator; the fraction thus formed, five seventeenths, is the amount the child of five should have of the average adult dose; five seventeenths of eight equals forty seventeenths, or two and six seventeenths, or about two and one third. Besides being more awkward to compute, the dose is somewhat larger.

Young's rule and this rule give exactly the same result for a child of eight; children younger than eight take a larger does by Young's formula than by this one, whereas children older than eight years take a progressively smaller dose. Did you ever stop to think that Young's rule never permits the adult dose, no matter how old the patient may be? With this rule the adult dose is reached at the age of twenty.

This rule is a modification of one worked out by Dilling, who divides the age by twenty in order to obtain the fraction of the adult dose required; or, for the metric system, he says to multiply the age by five and divide the product by one hundred in order to obtain the fraction of the adult dose required. It will be seen that the formula given for the metric system is similar to the one herein proposed, is equivalent to it, in fact, in outcome. But it is more simply stated in our formula, and is utilizable equally well for the English or metric system of weights and measures. Of course, if one thinks more readily or rapidly in vulgar fractions than in decimals, he can easily and quickly transpose his percentages into that form, making twenty-five equal one fourth, or sixty per cent. (the fraction for a child of twelve) equal to sixty one hundredths (equal to six tenths, equal to three fifths). No matter what may be the age of the child, the numerator of the fraction will always be a multiple of five; and since the denominator will always be one hundred, the resulting fraction will be an easy one to handle, and the computation from the adult dose an easy one to figure.

It will at once be asked how this percentage rule compares with Clark's rule. Clark's rule, it may be recalled, "is based upon the relative weight of the child as compared with the weight of the average adult." It assumes that the average adult weight is 150 pounds; it then states that if the weight of the child is divided by the adult weight (i. e., if the weight of the child is the numerator, and 150 is the denominator), the resulting fraction will be the correct proportionate part of the average adult dose for a child of that weight, regardless of age. For example, a child weighing fifty pounds should be given one third of the average adult dose. The percentage rule proposed runs fairly well with the average girl or boy under Clark's rule, but is not quite as accurate for the exceptional underdeveloped or overdeveloped child, though the variation here is not much more than the fractional portion discarded by Clark's rule. For example, under Clark's rule a child weighing fifty pounds would be entitled to three and one third grains, if the average adult dose was ten grains; but in round numbers three grains is the dose recommended. Now fifty pounds is the average weight for a child of seven; by the percentage rule, the dose for that child would be three and one half grains if the average adult dose was ten grains—a difference of one sixth of a grain from the result obtained by Clark's rule. However, a child of nine might weigh but fifty pounds if only forty-six inches tall, and a child of six might weigh fifty pounds if forty-six inches tall; but these exceptions from the average will be taken into account by the physician, and a modification in dose will probably normally be made to suit the individual case.

Appended are two tables showing the doses for the ages from one to twenty, in both the metric and English systems, when the adult dose is five grains or is one eighth grain, as determined by both the percentage system and by Young's rule; also, in table I. after the age of five, the age, height and weight of both girls and boys for a like dose as determined by Clark's rule.

From Table I it will be seen that Clark's formula is not equivalent for girls after the age of twelve, nor for boys between the ages of thirteen and eighteen; for to be equivalent it demands underweight of the average boy and overweight and height for the average girl. It is generally assumed that adulthood is attained at twenty-one; but if 150 pounds be taken as the average adult weight, then the boy at twenty-one must be seventy inches high, and the girl must be seventy-two inches tall. According to most tables, the average height of men is about sixty-eight inches, and that of women about sixty-four inches. If this is correct, then the average adult weight for men would be reached at about the age of thirty-four, and the same weight for women at about fifty-five. As these two conclusions are probably incorrect, being too low for the average weight of men and too high for the average weight for women, it would seem that the assumption in Clark's

rule that 150 pounds is the average adult weight from which the doses for those of less weight be computed, permits of wider error than the somewhat arbitrary percentage ratio. The percentage ratio takes it for granted that adulthood is reached at relative weight of the child, is substantially in agreement with the percentage formula from the age of five to adulthood; below the age of five it requires doses considerably larger than the percentage formula—over twice as large for the infant of one

twenty years of age; between the ages of one and twenty it divides the doses in strict ratio; it leaves to the physician's discretion further modifications to conform to departures from the physiological mean.

In Table II the equivalent to Clark's rule will be those of the average boy and girl; the dose corresponding is given in milligrams, and should be compared with the milligram dose for the same age under both the percentage formula and under Young's rule.

Table II shows that Young's rule is progressively inaccurate and inadequate after the age of twelve; it ought to be discarded. Clark's rule, based on the year; so the physician who adopts the percentage formula will be on the safe side in administering medicines to infants. Clark's rule also requires, for due equivalence to the percentage formula, undue robustness, in both girls and boys, from the age of seventeen; whereas the percentage formula assumes an average regular growth.

The relative simplicity of the metric measure over the English is brought out vividly in both tables, under either the percentage formula or under Young's rule.

Physicians would find it distinctly advantageous to adopt the percentage formula. It is simple and easy, and adequately accurate.

Simple Goitre in Children

ANNA S. WILNER, M.D.

New York

My original intention was only to report some cases of simple goitre in children, as any mention of this subject in the textbooks is conspicuous by its absence.

Though mention of this affection may be found as far back as Buddha, comparatively little is as yet known of the cause of the disease. A large number of dogmatic views explaining its origin have been advanced, but each one was replaced in turn by some other conception, which usually was supported more by the confidence of its advocate than by the validity of objective evidence. Some of the causes brought forth are almost fantastic in character, and are only of historical interest.

With the development of the study of the endocrine system, the nature and function of the thyroid is becoming somewhat clearer, and it is now considered one of the most important links in the chain of the glands of internal secretion. It controls metabolism and defends the body against infection. It is concerned with the metabolism of the iodine, storing part of it and distributing the rest. The iodine in the thyroid has been identified as a complex compound and is known as thyroxin. The blood supply of the thyroid is very rich, being five times as abundant as that of the kidney, and the whole volume of blood passes through the gland every hour. It is also closely connected with the sympathetic nervous system, and because of its rich blood and nerve supply, the thyroid is extremely vulnerable and is easily irritated and enlarged.

Medical tradition gives us forty-two causes for this enlargement. Water seems to have received the lion's share of the blame, and from time immemorial

goitre was considered a waterborne disease. Pliny mentions the fact that when young men wanted to evade military service, they drank water from certain wells for the purpose of developing goitre, and in Germany they spoke of the Kropfen-Brunnen.

Another etiological factor is the lack of iodine, which is still considered by weighty authorities on the subject as the cause of goitre. This theory is supported by the facts that the dwellers on the sea coast suffer comparatively little from this affection, due to the iodized air and the iodine found in the local salt and vegetation; and also by the fact that iodine is successfully used in the prevention and cure of goitre in men and animals. The faith in this theory is so generally accepted that one realizes the heresy in questioning it, and is only emboldened in so doing by certain facts which tend to break it. Well established phenomena, such as the decrease of goitre in fish when mercury or arsenic is placed in the fish tanks; the appearance of sporadic cases; the sudden outbreaks of epidemics; the prevalence of goitre in women; the development of goitre in soldiers and not in officers of the same division, are some of the facts which undermine the lack of iodine theory.

It is true that iodine when used in goitre of not too long standing, and in the absence of other pathological conditions, will often reduce the hypoplasia, for iodine, the principal compound of the thyroid hormone, reenforces this gland, which, owing to some interference, is no longer able to carry on its function of assimilating iodine. Thus one would be apt to infer that lack of iodine is not the cause *per se*, but that the addition of iodine is a remedy.

The search, then, for the etiology of goitre comes down to the search for the agents which interfere with the proper function of the thyroid. The indisputable facts like the sudden outbreak of goitre which is stopped by the change of water supply; the appearance of goitre in congested schools and barracks, which is ameliorated by improving the sanitary conditions; the occasional development of goitre after some infectious or focal disease; the experimental development of goitre in fish or animals when fed on the scrapings of fish tanks, or suspension of feces from a goitrous individual, all seem to point to a possibility of a common cause and lead one to consider goitre as due to some infection, be it bacteria or toxin. Some authorities lay it all to intestinal toxemia, substantiating their theory by reports of cases where goitre disappeared after the correction of the intestinal condition.

It is interesting to note that experimentally goitre can be produced in animals by overfeeding, especially when proteid food is used. There is evidently a closer relation between the condition of the organs concerned in digestion and assimilation of food, and the enlargement of the thyroid.

It has been asserted that goitre is caused by bacteria of the Trypanosoma family. But even the most enthusiastic advocates of the infectious theory, McCarrison among them, have not succeeded in isolating the specific bacteria or producing immunity, although they have made a serum. Though too little has been done in this direction for the findings to be taken as conclusive, yet from the study of the laboratory work of Dr. Frank Smithies, of Baltimore, who succeeded in demonstrating a low grade of infection in portions of the thyroid removed during operation; from the finding of infective and degenerative changes in the ganglia nerve trunks and endings in cases of toxic goitre, reported by Wilson and quoted by Frank Smithies, as well as from the well known characteristic of goitre above alluded to, one is inclined to infer that infection, though not fully understood, is nevertheless an important factor in the etiology of goitre.

The two apparently separate and distinct theories concerning the etiology of goitre, one of the insufficiency of iodine and the other of infection, are not only not distinct and independent, but are closely related and dependent upon each other. From the stated facts concerning the etiology of goitre, it is evident that there must be something—and that something of a toxic nature, which interferes with the normal function of the thyroid, and prevents it from assimilating sufficient iodine from the general economy, thus creating a state of iodine insufficiency. It is undoubtedly because of its disinfecting qualities that iodine is of therapeutic value in goitre. This disinfecting quality of iodine can most probably also explain the comparative infrequency of goitre among sea dwellers, for, being present in abundance in air and food, iodine acts as a detoxicant and inhibits the interference with the thyroid function. The question of etiology of the enlargement of the thyroid gland offers a wide field for speculation and surmise, as the entire subject of endocrinology is yet in its infancy. The most probable solution is that, owing to some interference, the metabolism is disturbed and a toxic condition is brought about. All toxic states exhaust the glands of internal secretion, and as the thyroid is the main detoxicant of the body, it bears the brunt of this condition, and is thrown into a state of dysfunction. The other glands undoubtedly also suffer in a greater or lesser degree, but owing to their anatomical position, they are not as easily observed.

So closely is the thyroid function connected with the general metabolism, that the only way to study the thyroid is to consider the patient as a biological whole, and the enlargement of the thyroid as a manifestation of some general disturbance. And it is only when we study the question of the enlargement of the thyroid from this angle, that we can understand how the various diseased conditions of the body may be contributing causes of the thyroid dysfunction, and can explain the occurrence of goitre following severe physical, nervous or mental strain, infectious and focal diseases, and especially the disease of the other glands of internal secretion. All these glands are closely related and mutually dependent upon each other, and as a rule, thyroid dysfunction follows any endocrinic disturbance, especially that of the ovary and the pituitary, with which it is synergistic. There is also evidently an intimate relation between the breaking up of the protein molecules and the thyroid function, for thyroxin is a compound of iodine and indol which is a split off the protein molecule by the intestinal bacteria. The thyroid hormone is also concerned with the intestinal flora, for in infants it appears simultaneously with the colon bacilli.

A few words concerning the enlargement of thyroid in women. The gland is slightly larger in the female, but normally it is at no time perceptible. The thyroid is frequently enlarged in girls at the time of puberty, and because of its occurrence at the time of life when the development is marked, the thyroid enlargement is spoken of as physiological. A careful study would show that this disposal of the subject is incorrect and is most unfortunate. Normally, the thyroid remains unchanged, or perceptibly so, all through the various periods of more marked growth of the body, as well as through the periods of strong emotions or infectious disease. The frequency of the occurrence of a certain condition should not make it physiological or normal, unless it is a constant nonfailing one hundred per cent. concomitant of a given process. This unfortunate nomenclature of physiological goitre may be responsible, to a great degree, for the neglect of the study of goitre.

Until recently the frequent occurrence of pains in the limbs of growing children, of acne in young people, of vomiting in pregnancy, of painful dentition, etc., were all looked upon with equanimity, and considered part and parcel of a physiological development. Deeper study, however, proved all these phenomena to be pathological and due to some metabolic disturbances of toxic origin. A closer study of goitre in young girls would also disclose some disturbing agent impairing the efficiency of the thyroid, which renders it incapable of carrying on its function. It would also disclose that the impaired functioning of the thyroid as demonstrated by its enlargement could, as a rule, be traced back to childhood. Owing to the fact that the thyroid grows slowly, and that the symptoms of the enlargement are extremely subtle, it often passes unnoticed, and is only recognized when it attains a considerable size.

The conditions that may cause this disturbance are manifold, and it would take us too far afield to enter into a discussion of the shortcomings of the educational, industrial and social systems responsible for the interference with the normal development of the child and youth. Suffice is to say that these unfavorable conditions are responsible in a great measure for a physical, emotional and mental overstimulation which interferes with the metabolism, and brings about a socalled toxic state, which, in its turn, causes an irritation and enlargement of the thyroid. The appearance of a goitre is no more physiological at puberty than at any other time, and it is always a pathological condition.

There may be some weakness or peculiarity in the organ of the female which accounts for the frequency with which the thyroid becomes the seat of pathological changes—most probably something that is being transmitted from generation to generation. As it is so closely related to the sexual organs, it probably partakes of the vulnerability of the latter, which are known to fall a prey to irritation and disease more quickly in the female than the male. There may also be a possibility that the anatomical peculiarities of women, namely, the proximity of the anus to the vulva with its abundant blood and lymph supply, numerous glands and mucous membrane, which afford continuous opportunity for a low grade of infection, causing an attenuated toxic state, may have some bearing upon the subject. If there should be any value in this hypothesis, some light may be thrown upon the prevalence of goitre in the female. The same factor may serve to explain the well known prevalence of pyelitis in the female. The higher emotional temperament in the female which, through the sympathetic nervous system, affects the volume of the blood supply of the thyroid gland, is undoubtedly also a contributing cause of irritation and consequent morbidity of the thyroid. These remarks would show that the subject of the cause of goitre, and especially its prevalence among women, is as yet a *terra incognito,* and indicate an urgent need for further study.

As simple goitre is not a fatal disease, its pathology can only be learned by the study of the thyroid as well as all the endocrine glands at all autopsies. If it were permissible to divert, I would here make a plea for the urgency of the education of the general public to the realization of the great value that lies in autopsies. One fully realizes the strong wall of opposition created by ages of religious training and superstition. Yet when the public is brought to understand that only by means of postmortem observations can knowledge concerning goitre be obtained, which might have prevented many early deaths, will opposition to autopsies gradually give way.

Whatever the ultimate cause of goitre will be found to be, it is an undisputed fact that it is on the increase and is indeed a menace to public health.

The growth of goitre is so slow and insidious, and its deleterious effect upon the body is so subtle and gradual, that it is frequently allowed to pass unnoticed, or when noticed is usually neglected. Yet a person with a goitre is undoubtedly below par, as the goitre, itself a result of some infection, renders the body more prone to other infections. The enlarged thyroid is likely to become the seat of colloid degeneration, adenomatous changes and malignancy. There is always a probability of the simple goitre taking on a toxic character and Graves's disease developing. The size of the gland has no direct bearing upon its activity. In the light of the present state of knowledge of the etiology of goitre, it is difficult to say whether the enlargement is due solely to irritation or is compensatory in nature, or is the result of both.

According to Nicola Pende, an enlarged thyroid is not always an overacting gland, but, on the contrary, is often in a state of hypofunction as the enlargement in many cases is due to an increase in the colloid substance, causing a decrease in the amount of the secretion of the active principle. This is well borne out by the known fact that few of the endemic goitres, which are usually large, develop Basedow's disease, and when they do, it is of a mild type. A careful study of the goitrous patient would show that there is always some deviation from the normal, and even the laity connect the presence of goitre with nervousness. The well known syndrome of neurasthenia may often be due to a latent condition of thyroid dysfunction, and any undue strain is likely, in some cases, to cause an explosion and produce a more or less serious form of Graves's disease. In short, goitre is a pathological

condition of varying severity and must be dealt with accordingly. Furthermore, there also lurks the danger of this condition affecting the offspring as the thyroid is apt to become gradually less active in succeeding generations. Statistics show that offspring of goitrous individuals are liable to myxedema and cretinism, and it is even claimed that the number of deaf mutes among them is higher.

It is held that goitre is one of the easiest diseases to prevent, for the administration of iodine has proved successful in both men and animals. While the use of iodine should be urged, we must not let ourselves be blinded by its effects, and remember that though it is quite frequently effective, it is so merely because it supplies the thyroid with the element which, under normal conditions, it should have elaborated from the general economy.

The eradication of goitre is to a great extent a communal problem, and the fact that many communities in various parts of the world have appointed goitre commissions, is evidence that they realize both the seriousness of the situation as well as their duty to ameliorate the condition.

In view of the large number of goitres found in children of school and even preschool age in this country, as well as abroad, it is most difficult to explain why practically no mention of the condition is made in textbooks published prior to 1923, for the careful attention given to other affections would preclude the possibility of accusing the author of lack of observation. Such absence is probably due to the fact that ordinarily goitre gives no marked clinical symptoms in childhood, and the child so affected is considered a well child. The study of the normal and apparently normal child is but in its infancy, and therefore the child who as yet shows no ill effects from the enlarged thyroid is as a rule overlooked. It is unfortunate that its presence is not discovered earlier, for the sooner the source of the irritation is found, the better are the chances of establishing proper metabolism and helping the normal development of the child. Since the condition of the thyroid is a clue to the child's general health, no examination of the child should be considered complete without an examination of the thyroid.

So likely are the physicians to pay no heed to the condition of the thyroid in the child, that not only are simple goitres overlooked, but even toxic goitres often remain unnoticed, and the affected child is merely classed as nervous and below par. One of such cases coming to the notice of the writer seems worthy of mention. While visiting a relative at a private boys' summer camp, a small thin lad of eleven, who noticeably lacked the poise of an ordinary camp boy, was pointed out as an exception in his response to the usual feedingup method employed in camps. Even a superficial examination of the child revealed quite a prominent thyroid, slightly protruding eyes, and tremor of the hand.

REPORT OF CASES

Case I.—Ruth S. had a "swelling in her neck" since she was about six years old. Had measles and chickenpox when a baby; otherwise was always well. Is ten years of age now, is well developed and has a prominent enlargement of the thyroid.

Case II.—Marie S., Ruth's sister, also had an enlarged neck since early childhood. Was an exceptionally well child, only was subject to frequent colds. Had chickenpox and measles when two years old. From the time she was six years old, she had had frequent attacks of tonsillitis. She is now thirteen years of age; is well grown and has a prominent goitre.

Case III.—Katherine L. had an enlarged neck since she was five years of age. She had suffered from obstinate constipation since babyhood. Had none of the children's diseases before the appearance of the large thyroid. The mother stated that she suspected that the child might have goitre, but as her own sister had something like it since early childhood and seemed well outside of being nervous, she paid no attention to it. Katherine had most of the children's sicknesses—all in a light form. She suffered from chronic bronchitis from the age of eight, and was cured by a winter in Texas. Is thirteen years old now, well developed, irritable and nervous, and is still suffering from constipation. Has quite a large goitre.

Case IV.—Mathilda A. always had a large neck, according to her mother's statement. A physician was consulted, who told her that the child would outgrow it. At six years of age had pleurisy and empyema; frequently complained of pain in the legs since she was eight years of age. The latter was attributed by a physician to the fact that the child was growing too fast. Mathilda is twelve years old now; is large for her age. Has a large thyroid.

Case V.—John B. had an enlarged thyroid from the time he was four and one half years of age. Was well as a baby. Had pyelitis at two, and a slight throat infection at three, which was mistaken for diphtheria and treated by an overdose of antitoxin. Reaction was unfavorable, and the boy showed a slight rise in temperature for several weeks, pointing to some low grade of infection which could not be located. The boy seemed to remain in a poor condition for a long while. Had a severe ear infection at four years of age, and about six months later the thyroid began to grow larger. Removal of the tonsils at five and one half had no effect upon the thyroid. Child showed a lack of resistance to infection; developed a cellulitis from a slight scratch; synovitis in the hip joint from a fall; a gangrenous appendix which developed within ten hours. Had good recuperative power and recovered quickly. The boy is nine years of age now, is well grown physically and mentally; is of an emotional nature. Has quite a prominent thyroid which seems to become larger after any strain or emotion.

Case VI.—Alice H. began to show an enlargement of the thyroid from the time she was four years of age. Previous to the time of the appearance of the goitre, suffered from frequent colds, an attack of bronchitis, and otitis media. Continued to be susceptible to colds; had an attack of pyelitis, vaginitis, and a slight nephritis. When eight years old had her tonsils and adenoids removed and bad teeth extracted, without any effect upon the thyroid. Is ten years old, is rather small for her age and underweight; is extremely intelligent. Has a prominent enlargement of the thyroid.

Case VII.—Mollie L.—The enlargement of the thyroid was first noticed when the child was about six and one half years of age, a half year after she had sustained a fracture of the elbow. There is a history of some bowel trouble when a baby, with a slight attack of scarlet fever. Had no serious illness since the accident; troubled with a twitching of the eyes. Is nine years of age now—tall for her age; is pale. Has a slightly enlarged thyroid.

Case VIII.—Ruth E.—Up to five years of age, was an exceptionally well child; well grown and a good eater; is stubborn and hard to manage. When six years old had an attack of capillary bronchitis and an otitis media. An enlargement of the thyroid began to develop, which continued to increase noticeably for about a year. Enuresis appeared at the age of seven. General health continued to be good. Is eight years old now and thyroid is enlarged, though slightly smaller than it was.

Case IX.—Jane P. had an enlarged neck from seven years of age, varying greatly in size at different times. Child had measles when a baby. Suffered from frequent attacks of indigestion and was always undersized. At twelve years of age, girl was strikingly small for her age, anemic and nervous. Thyroid was prominent. Is now fourteen years of age, has grown a good deal in height, gained in weight—condition of blood improved—thyroid decidedly smaller though still slightly enlarged.

Case X.—Marie C. always had an enlarged neck, for she remembers that her schoolmates in the primary grades used to remark about her large neck. Had the children's sicknesses in light form,—otherwise had apparently good health. Is twenty-five years old now, suffers from nervousness and irritability, and is considered a neurasthenic. Has a large goitre.

Case XI.—Sophie M.—According to her mother, "Sophie always had a very stout neck, but as she always was well and ate heartily," her mother said, "there was no use in looking for trouble." Child was seen first when eight years of age. Had quite an enlarged thyroid. When ten years old was brought to the office for treatment, for her mother then thought that child's neck had grown too stout. Is a large child for her age; of rather low intelligence, with that peculiar cunning that persons of low mentality often have—is stubborn. Is eleven years old now—thyroid is large.

Case XII.—Alice M. had an enlarged thyroid from the age of five. Had no serious illness; suffered from constipation; had mild attack of measles when four and one half years old. At ten years of age had articular rheumatism with endocarditis—recovery slow. The girl is now twenty years old—is well grown, anemic, nervous and has valvular heart disease. Thyroid is much enlarged.

Case XIII.—Minnie F.—From the time she was seven or eight years of age remarks were frequently made about her large neck. Was always well grown for her age. Was frequently ailing and had most of children's sicknesses; habitual constipation; frequent colds and sore throats. Is eighteen years old now—tall, muscles poorly developed; is pale; has enlarged tonsils, and bad teeth; has chronic appendicitis; an irregular heart; is extremely nervous and is classed as a neurasthenic. Has a large thyroid.

Case XIV.—Sadie F. had an enlarged neck from about eight years of age. She remembered that when a little girl, high neck dresses would not fit her. Was always considered cranky. Suffered from constipation and frequent colds; was never very strong—menstruated at sixteen years. The patient's sister has also goitre from early childhood. At nineteen the goitre became large and she was operated upon for it.

Case XV.—Eleanor D. had an enlarged neck ever since early childhood. No attention was paid to it as she developed apparently normally. As a baby had severe bowel trouble; had a slight attack of diphtheria and mumps at five. Is thirteen years old now—is tall and thin—is a poor eater, is bright and ambitious. Has quite a large goitre.

Case XVI.—Elizabeth S.—According to her mother's statement, the child always had a prominent neck, but as the mother's sister was similarly affected, and was apparently well, she felt no concern about her daughter. Child had pneumonia at six years of age, and scarlet fever at eight. When twelve years of age, an irregularity of the pulse was discovered, which fact, as well as the enlarged thyroid, was attributed to nervousness. Came under observation at fifteen years of age. Is now sixteen years old; is extremely nervous; is suffering from digestive disturbance; has a rapid and irregular pulse. Has a large thyroid.

PROGNOSIS

The prognosis of simple goitre in children is good as far as mortality is concerned, but unsatisfactory as to its eradication.

TREATMENT

The treatment of the cases reported consisted in searching and correcting as far as possible any condition showing deviation from normal, in building up the general health, and in the administration of iodine or of thyroid extract where the nervous and circulatory condition did not contraindicate their use. The result varied with the cooperation of parents or patients. In none of the cases under observation, not even in those where the treatment began at the inception and extended over a period of five to six years, has the goitre disappeared entirely, though in some it has perceptibly decreased. The removal of tonsils did not seem to have much effect upon the size. Though the number of cases observed is too small to warrant the making of general deductions, the rather unsatisfactory result of their treatment only emphasizes the importance of prophylaxis.

A SUMMARY OF THE TWENTY CASES OBSERVED

There were nineteen girls and one boy. The age of the children at the time the enlargement of the thyroid was first noticed ranged from four to eight. The majority of the children were well grown for their age. In many cases there was a history of goitre in the family. A great number of them suffered from constipation.

There was usually a history of some infectious disease or local infection prior to the appearance of the condition, but the frequency with which chil-

dren suffer from these diseases, as well as the comparatively small number of cases under consideration, preclude the making of any deduction as to their etiological significance.

The growth of the goitre was as a rule progressive but slow—occasionally it was of a transitory nature, the relapses being caused by a temporary congestion of the thyroid from some strain or emotion. The enlargement did not disappear entirely in any of these cases. It either persisted after puberty was well established or even kept on getting larger. In some cases, however, the enlargement became smaller as the child developed and grew stronger with the advance of puberty.

CONCLUSION

1. Goitre is on the increase and is a menace to the health of the present and future generations.

2. The etiology of goitre is as yet not well established though overwhelming evidence is pointing to some factor of an infectious nature.

3. The endocrine glands should be studied during every autopsy, and more postmortem examinations should be encouraged.

4. The prophylaxis should embody the strictest attention to public, home and personal hygiene in its widest scope, and until the primary cause of goitre is found, iodine should be administered to all expectant mothers in goitrous regions and to goitrous mothers everywhere, to small children in goitrous regions, and to all children everywhere showing the slightest tendency towards the enlargement of the gland.

There is one thing that must be borne in mind, and that is as malaria was not considered a conquered disease until the plasmodium was found, and syphilis not until the spirochetes were discovered, notwithstanding the fact that remedies for both affections had been known for ages, so will goitre remain invincible until the true cause of it is found.

30 EAST FIFTY-EIGHTH STREET.

Pyelitis in Infants and Children*

A. HYMANSON, M.D.
New York

I shall first outline the diagnosis and treatment of pyelitis as it is encountered in daily routine, and then state some of the recent developments of our knowledge from the laboratory and the clinical experience of the urologist.

In the experience of the pediatrist pyelitis is diagnosed almost entirely from the urinary findings, and here I may insist that the difficulties of obtaining the urine of the young child have been greatly exaggerated. The use of cotton to collect the fluid is not practicable, because the formed elements of the urine are strained out and the test urine is a clear solution which is available only for chemical tests. For collecting urine I use a widemouthed bottle for girls and a test tube or condom for boys; these containers to be strapped to the body with adhesive plaster. As a reserve resource we have, of course, the use of the catheter. Urine obtained by any of these methods should neither be allowed to deposit nor be centrifugalized, because we do not want a concentration of the formed elements for microscopic study, but a suspension of these in the fluid portion. What is wanted is a leucocyte count of this suspended urine. From another angle, if the urine stands, alkalinity, should this be the reaction, may dissolve the leucocytes. If there are as many as six leucocytes or more to the microscopic field the diagnosis of pyelitis may be confidently made. Some clinicians even regard two leucocytes as suspicious of pyelitis. Examinations should be followed up for several days, and at least one examination on each of three successive days before a final diagnosis, because one or two tests may be negative even if the disease is present.

*Read before the Eastern Medical Society of the City of New York, April 13, 1923.

Having made our diagnosis the treatment should be as follows: rest in bed, sponge or lukewarm baths for hyperpyrexia. An abundance of fluid should be given, for a seven months old child about one pint of water, to an older child two pints daily. If fluids cannot be given by mouth, they can be supplied through stomach or nasal tube or by enteroclysis. Should vomiting persist, hypodermoclysis must be resorted to. Enough water must be given so that specific gravity of the urine is below 1012.

As to food, young infants should receive milk diluted with alkaline water, some cereal and fruit juice. Older children may have bread and butter, cereals, stewed fruit, cooked vegetables, and pudding. Göppert and Langstein give, in the afebrile pyelitis cases, meat and eggs in addition to the foods mentioned above.

Most cases of pyelitis in children are due to the bacillus coli which flourishes best in an acid medium. Alkalies should be freely administered, these also having a diuretic effect. Potassium citrate well diluted is given in doses proportional to the age of the child beginning with fifty to one hundred grains daily in divided doses and increasing to one hundred and fifty grains if necessary. The only way to determine the proper dose is by watching the reaction of the urine. As soon as the urine becomes strongly alkaline, and the fever and other symptoms subside, the dose should be diminished. At times it is difficult to alkalinize strongly acid urine by ordinary doses of potassium citrate, and large doses will occasionally upset the stomach and cause diarrhea. This drug must be substituted by sodium bicarbonate, two or three teaspoonfuls in twenty-four hours divided into six or seven doses. Moreover, sodium bicarbonate may be added to food to disguise its bad taste and

may also be given per rectum: two or three ounces of a five per cent. watery solution, every two or three hours, until the urine becomes alkaline. If after ten days of treatment no benefit is apparent, urotropin should be substituted in daily doses of fifteen to twenty-five grains suitably divided. But when this drug is given, an acid concentration of the urine is desirable, otherwise the formaldehyde which exerts the antiseptic effect will not be broken off from the urotropin. To obtain this acid concentration, we should give large doses of acid sodium phosphate, twenty-five to forty grains daily, of course in divided doses. The urotropin treatment should also be given for ten days, after which if there is no further improvement a return to alkaline therapy may be indicated.

Should the case still be obstinate one may try vaccinotherapy, but aside from a slight transitory improvement, I have never seen positive results from this method, nor has bladder irrigation been of service unless cystitis is actually present. It must be borne in mind that while the patient may be clinically cured, the urine may still contain pus and bacilli.

Quite recently Cowie (1) has obtained some good results from protein therapy. He used horse serum in nine patients with apparent success and in two of these cases the pus disappeared completely from the urine after the third injection of three c. c. of the serum.

For the sake of completeness I may now quote from the province of the laboratory worker and urologist.

According to laboratory investigators our knowledge of simple or uncomplicated pyelitis in early life is incomplete. Few die of this affection, and thus few autopsies are on record. Most pyelitis seems to be associated either with nephritis or cystitis, so that the clinical picture of uncomplicated cases is difficult to obtain. Of great interest is the remote prognosis. Owing to the tendency to spontaneous recovery it is difficult to isolate any form of efficacious treatment, but it is often found that the recovered patient still has pus in the urine (or bacilluria), and it has been thought that these latent cases are responsible for much of the pyelitis of adolescent and adult years, including pyelitis of pregnancy. The evidence both for and against this supposition is considerable and, of course, is too conflicting to permit of a decision.

With the advance of clinical urology it has become inevitable that the subject of pyelitis in childhood appears on the borderline between urology and pediatrics. It has become possible to cystoscope even male infants, and to perform ureteral catheterization at the same time. Naturally only the severe and persistent case which has been refractory to milder methods should be the one to reach the urologist, but when we consider that these severe forms are usually complicated with nephritis or cystitis it is conceivable that any case of pyelitis may be looked on as essentially surgical. The use of the x ray is also valuable for excluding the presence of stone. It is evident that pyelitis due to stone should be promptly recognized before any treatment is instituted.

In making a diagnosis it is also important to distinguish between ascending and hematogenous forms of pyelitis, a subject of which our knowledge has been more or less speculative. In order to throw light upon it, considerable experimentation has been carried out in recent years and we now have a fairly clear idea of the distinction between the two. It has been shown in the rabbit that after blood infection, lesions appear in the cortex of the kidney and the papillæ of the pelvis. In fact the pelvic lesions are sharply localized in the papillæ, the lateral aspect being free. The exact opposite is seen when infection from the bladder has been set up, for now the papillæ are free and the rest of the mucosa infected. It is not necessary that the infection be carried up through the lumen of the ureter, for it may occur through the surrounding lymphatics. Helmholz, formerly associated with Kretschmer of Chicago and now with the pediatric department of the Mayo clinic, is a leading experimenter along these lines, and his results have been corroborated from outside sources.

Experiment has shown that while obstruction in the urinary tract below the kidney pelvis may favor the development of ascending pyelitis, the latter may occur in its absence from causes which are not fully understood. In like manner, if there is a case of pyelitis of unknown origin, the presence of coli bacilli or infectious cocci in the blood is not conclusive evidence of a hematogenous origin. Ascending pyelitis may be brought into etiological relationship with the known fact that the urine in the bladder may at times regurgitate into the kidney pelvis, not only in diseased conditions but in the normal subject. Any condition which causes thickening in the wall of the bladder or in the ureter may conceivably be responsible for this regurgitation—anything whatever which can cause partial obstruction of the urinary tract below the pelvis.

Helmholz states that there is absolutely no correlation between the clinical symptoms and pathological findings of pyelitis, because of the fact that very different conditions cause the same syndrome. He adds that a clinical diagnosis of pyelitis simply cannot be made with any degree of certainty. Many conditions which involve pyelitis have but a single symptom in common, pyuria. In regard to the active rôle of the Streptococcus lacticus in these cases, as shown apparently by Langer and Soldin, Helmholz was unable to confirm the existence of this association; for he found this germ in only a small number of his cases. In the majority, especially when solid culture media were used, the results were negative. The well known pediatrist Thiemich of Breslau records that in the cases of clinical diagnosis of pyelitis the bladder and kidney pelvis were often found normal at autopsy while the kidney was the seat of lesions. This statement seems to be upheld by the results of experiment on animals. Abscess of the cortex (glomeruli) of the kidney seems to be mistaken for pyelitis in the clinic, and we have seen that in hematogenous infection, renal lesions are found in association with papillitis (medullary portion).

In regard to treatment, Kretschmer and Helmholz (2) showed that pyelitis could be treated even in young infants, including boys as well as girls, by

washing out the kidney pelvis with a solution of nitrate of silver, after diagnostic use of the cystoscope and preliminary x ray to exclude the possibility of stone in the pelvis. Another disease which must be excluded before lavage, is renal tuberculosis, and by the usual tests, comprising bacteriology and inoculation experiments. Naturally, only the chronic case rebellious to ordinary measures is subjected to instrumental intervention. The criterion of cure in these as in all cases must be, that the urine is rendered sterile and free from all formed elements. Absolutely no attention should be paid to ordinary freedom from general symptoms, for perfect health seems compatible with latent microbism in these cases.

In comparing my personal experience with the findings of the laboratory man and urologist there may seem to be considerable want of harmony, but this is readily explained. It is not denied anywhere that mild measures usually suffice in pyelitis, for the latter has a strong spontaneous tendency to recover. In obstinate cases and when the urine refuses to clear up despite the apparent good health of the patient, the case, in theory at least, could be transferred to the urologist, but the urological treatment of infants is not only extremely drastic but only a small number of specialists have thus far resorted to it and it is doubtful if it ever comes into familiar use. Apparently few men have practised cystoscopy and ureteral irrigation on boy babies and young male children and if these methods are ever commonly used they will doubtless be limited to the obstinate case.

A Simple Method of Preparing Lactic Acid Milk*

M. BERNARD BRAHDY, M.D.
New York

During the past year, many articles have been written on the results obtained in the feeding of infants with lactic acid milk. All reports which I have found state that the milk formulæ were prepared according to the method described by Marriott and Davidson in 1923 (1). This method is to add lactic acid (U. S. P.) drop by drop to the boiled cooled milk, stirring continuously, followed by the addition of corn syrup. This necessitates great care on the part of the mother, and consumes much time, especially, as happens frequently, more than a hundred drops are necessary. Gleich (2) suggests that the milk mixture be stirred six times between the addition of each drop of lactic acid and that it should take at least twenty minutes to make a pint of the formula. He states that in many cases both in the dispensary and in private practice he was compelled to change his lactic acid formulæ to other mixtures, mainly it seems to me, because the formulæ were not made properly. In our dispensary, it was formerly difficult, even with the able assistance of the social service department, to teach mothers how to prepare the formulæ properly by the drop method.

For some time we have been using a simpler method, which is easier to explain to the mother, reduces the time of preparation to a few minutes, and gives a finer curd when finished than is obtained by the drop method. It consists of mixing in a cup the desired amount of corn syrup with an equal quantity of water, and the prescribed amount of lactic acid. This acid syrup mixture is then poured into the milk (boiled or raw as desired), or milk and water, and stirred for a minute.

No special care is needed in adding one solution to the other. There is no difficulty in making the mother understand this method. We explain it to her in the dispensary, and in almost all cases the social service worker on her visit the next day, has found that the mother was preparing the formula correctly. It takes less than five minutes to make any amount of a formula. The patients who have been on mixtures prepared by the acid syrup method, have shown as good result clinically, as those kept on mixtures prepared by the drop method. Dr. A. Waltz of this hospital has made hydrogen ion determinations and reports (personal communication) that the resulting hydrogen ion concentration is the same in the two methods of preparation.

We are now using the acid syrup method of preparation for ward cases. A stock syrup solution as suggested by Marriott (3) consisting of forty-five parts of corn syrup and fifty-five parts of water is used for convenience. This gives about one ounce of sugar by weight for each two fluid ounces of syrup solution. The required amount of acid is mixed with this diluted syrup. The acid syrup mixture is then poured into the milk, stirred a few times, and is ready for the bottle.

SUMMARY

I have described a method of preparing lactic acid milk which is easy to explain to the mother, saves time, and gives results which are satisfactory. The method, although not original with me, is published because I believe it will be of value to the profession.

When your patient has used six Bell-ans dissolved in a glass of hot water to relieve the immediate symptoms of digestive disorders you can proceed at once with the thorough examination and systematic treatment of the case upon your arrival. Bell-ans is never recommended as a cure for indigestion but thousands of doctors know that Bell-ans gives immediate relief.

Bell-ans is now universally used.

A Physiological Corrective of Constipation

OF ALL the countless measures offered for the relief of chronic constipation, there is none that can be more properly considered a true physiologic corrective of intestinal torpor, or that can be more implicitly relied on to restore normal functional activity to the inert bowel, than

AGAROL

REG. TRADE MARK U. S. PAT. OFF.

COMPOUND

The gratifying results that uniformly follow the use of this noteworthy product are not at all surprising, in view of its composition—pure mineral oil, agar-agar and phenolphthalein.

How well Agarol Comp. meets every test will be demonstrated in no uncertain way by its consistent use in some stubborn case of constipation. Administered in systematic dosage, it mixes with the feces, making them soft and plastic, and increasing their bulk. Under this condition, the intestinal contents furnish the natural impulse to peristalsis, and this, with their incidental lubrication, assures their ready passage and easy evacuation.

Continued over a reasonable period, Agarol gradually restores the bowel to a point where it can perform its physiologic functions unaided. Because of this, together with its freedom from griping or other disagreeable effect, Agarol will be found superior as a remedy in the treatment of constipation, no matter how chronic or whatever may be its cause.

Points to Remember—

Agarol is the original mineral oil — agar-agar emulsion, and has these special advantages:

It is perfectly stable, odorless and palatable. It causes no griping, nausea, or any disturbance of digestion or nutrition. It mixes freely with the bowel content; it lubricates without leakage of oil.

No limit of age, season or condition restrict the use of Agarol with safety. It contains no sugar, saccharine, alkalies, alcohol or hypophosphites.

A liberal supply for testing will be sent to physicians on request.

An ally of preventive medicine—
KELLOGG'S ALL-BRAN

RIGHT in line with the objective of modern medicine is Kellogg's ALL-BRAN, cooked and krumbled.

It is an ally in preaching the ounce of prevention rather than the pound of cure.

Its purpose primarily, of course, is the relief of constipation. And because it is **ALL BRAN**—not mixed with other elements—it accomplishes the results you expect of it.

Kellogg's ALL-BRAN is equally valuable in preventing constipation—in keeping the intestinal tract open, and functioning naturally.

It will be eaten regularly, too, on your prescription. Kellogg's ALL-BRAN has a most appetizing flavor—totally unlike ordinary, unpalatable bran.

We consider it a pleasure to send any physician a full-size package of Kellogg's ALL-BRAN, without obligation. A request on a postal is sufficient.

Nature's Way *vs.* Man's Way

Nature has so arranged that mild acids, like fruit acids, bring the following benefits to teeth.

They curdle fresh mucin plaque. They act to disintegrate plaque at all stages of formation.

They increase the alkalinity of the saliva, which is there to neutralize mouth acids.

They increase the ptyalin in saliva, which is there to digest starch deposits on teeth.

They increase the saliva's flow and fluidity, which serve to cleanse the teeth.

Some almost immune

Peoples whose dietary consists largely of fruit are notably less subject to caries. Some, like the Sicilians, are almost immune. But those who eat much starch and little fruit rarely escape tooth troubles.

Pepsodent aims to correct those deficiencies to the extent that a dentifrice can.

Old vs. modern ways

The old idea was to apply an alkaline dentifrice, containing soap, or chalk or magnesia. Thus to combat mouth acids in a momentary way. The result was to reduce the alkalinity of the saliva, reduce its ptyalin index, its fluidity and its flow.

Pepsodent acts on the opposite principle. It follows Nature's way. Its mild acidity brings effects like fruit. Thus it increases Nature's protecting agents, which are ever-present.

As a result, dentists of some 50 nations are advising Pepsodent today. Dental authorities the world over agree with its principles.

If you are not fully informed about Pepsodent, please send for our latest literature, based on 8 years of tests.

with

AGAR

At the suggestion of a number of our friends in the medical profession who prefer in certain cases to prescribe Liquid Petrolatum in the form of an emulsion, we are presenting for your attention — Nujol emulsified with Agar. This product is intended for prescription use only.

Our Research Laboratories have been working for a considerable time to perfect Nujol with Agar. And rigid tests have demonstrated that in quality, suitability and purity it is unsurpassed.

Nujol with Agar is a perfect emulsion. It contains no cathartic ingredient, its action being entirely mechanical. Moreover, its creamy smoothness and pleasant flavor render it highly palatable, particularly to children.

Test Nujol with Agar yourself. A sample will be sent you on request.

Antiphlogistine poultice, some hours after application to inflamed area. Centre is moist, where exudate has been drawn from the congested tissues. Periphery, covering normal surrounding tissues virtually dry.

This chart shows the Osmotic action of Antiphlogistine

DIAGRAM represents inflamed area. In zone "C" blood is flowing freely through underlying vessels. This forms a current away from the Antiphlogistine whose liquid contents therefore, follow the line of least resistance and enter the circulation through the physical process of endosmosis.

In zone "A" there is stasis, no current tending to overcome Antiphlogistine's hygroscopic property. The line of least resistance for the liquid exudate is therefore in the direction of the Antiphlogistine. In obedience to the same law, exosmosis is going on in this zone, and the excess of moisture is thus accounted for.

Antiphlogistine generates and retains heat upwards to 24 hours

Due to the chemical reaction which goes on during Osmosis between the c. p. glycerine of Antiphlogistine and the water of the tissues, Antiphlogistine keeps up a steady heat generation.

This sustained heat is invaluable; relieving congestion by increasing superficial circulation, stimulating the cutaneous reflexes, and causing contraction of the deep-seated blood vessels.

Used by hundreds of thousands of physicians the world over.

Antiphlogistine stands alone as a non-toxic, non-irritant abstractor of fluid exudates in superficial inflammations. It relieves deep-seated congestion by inducing superficial hyperemia, through its inherent hygroscopic property, and without irritation.

Let us send you our free booklet "The Pneumonic Lung." Address The Denver Chemical Company, Dept. A, New York, U.S.A. Branches: London, Sydney, Berlin, Paris, Buenos Aires, Barcelona, Montreal.

USEFUL LILLY ITEMS
In Treating Diabetes

ILETIN (INSULIN, LILLY)

Pure - Stable - Constant in Unitage

As a result of two and one-half years research and experience in the manufacture of Iletin (Insulin, Lilly) and in the production of very large lots, we have been able to develop a system of standardization which insures constant unitage within narrow limits. The capacity of the Lilly Laboratories is equal to practically any conceivable demand.

Iletin (Insulin, Lilly) is supplied through the drug trade in 5 c. c. ampoule vials: U-10, U-20 and U-40 containing 50, 100 and 200 units respectively.

IMPORTANT ACCESSORIES

Iletin Syringes
Specially constructed for the administration of Iletin (Insulin, Lilly), graduated in units instead of minims.

Urine Sugar Testing Outfit
A convenient portable set for quantitative tests. The amount of sugar can be determined easily and quickly. Complete directions accompany each set.

Saccharin Tablets
Used by diabetics as a sweetening agent where sugar is prohibited. Supplied in 1-4, 1-2, 1 and 2-grain tablets in bottles of 100 and 1000, also in pocket flasks.

Ampoules Glucose
A valuable emergency measure in treating diabetes and other conditions.

Benedict's Solution
Supplied both for quantitative and qualitative tests.

Plain Agar, Granular
Prepared without sugar. A harmless mechanical and natural stimulant to the bowel. Distinct from Prepared Agar, Lilly. Supplied in 1-4 and 1-pound packages.

Physicians will be supplied additional information on any of these items on request.

All Lilly Products are supplied by the Drug Trade

NEO-TREPOL in SYPHILIS

At the first Congress of French speaking Dermatologists on Syphilology held in Paris in June, 1912, there were thirteen separate reports on the treatment of syphilis with bismuth salts. Clinicians from France, Spain, Brazil and Denmark reported striking therapeutic results from the use of this drug.

In January, 1922, Levaditi and Sazerac published their experience of over a decade with bismuth in syphilis.

Numerous original reports reiterating the therapeutic value of bismuth in all manifestations of syphilis have appeared in many journals abroad.

In June and October, 1923, reports by American observers published in the Archives of Dermatology and Syphilology (U. S. A.) confirmed the results obtained in other countries.

NEO-TREPOL (CONTAINING 96% OF BISMUTH) IS THE ORIGINAL PREPARATION USED BY LEVADITI & SAZERAC.

NEO-TREPOL is given intramuscularly, the injections are *painless* and there are *no reactions* or *after effects.*

NEO-TREPOL is being used extensively in Hospitals, Clinics, and in private practice throughout the United States and Europe.

A Reprint of the Article by Dr. C. Levaditi from the Pasteur Institut, Paris, Which Appeared in the March 31st, 1923, London Lancet Will Be Forwarded Upon Request.

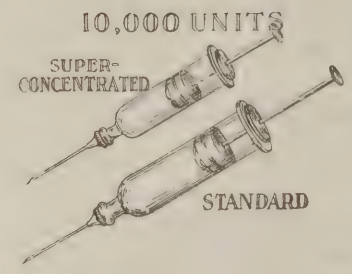
Three Essentials



Super-Concentrated Diphtheria Antitoxin

For curative treatment and immunization of contacts.

An antitoxin of very low protein content, small bulk, highly refined, which minimizes serum sickness, and is rapidly absorbed.

Less bulk—Less pain—Quicker results.

DOSAGE—1000, 3000, 5000, 10,000, 20,000 units.

Supplied in Mulford Perfected Syringes, ready for immediate use.

Diphtheria Toxin-Antitoxin Mixture

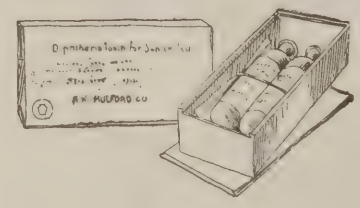
To produce a lasting immunity, which develops in about eight weeks and continues effective for some years, probably for life.

Immunization of children of pre-school age and up to 10 years is recommended.

DOSE—3 injections of 1 cc each, at 7-day intervals.

Supplied in packages containing

3-1 cc vials (1 immunization).
30-1 cc vials (10 immunizations).
10-cc vials (3 immunizations).
30-cc vials (10 immunizations).



Schick Test Toxin

To determine susceptibility to diphtheria.

DOSE—0.1 cc injected between the layers of the skin.

Supplied in packages containing sufficient material for 50 tests.

THE PIONEER BIOLOGICAL LABORATORIES

MERCODEL

Its Chemistry 3.

Mercodel contains pure metallic mercury uncombined with any organic or inorganic radical or compound.

Since metallic mercury is quite insoluble in water, the therapeutic results that it gives arise evidently from some source other than ionization of the mercury in water.

Metallic mercury is soluble in fats and lipoids.

The proof of the solubility of metallic mercury in animal and vegetable fats and lipoids is shown in figures 1 and 2 of our descriptive leaflet.

Because metallic mercury is soluble in fats and lipoids, but is not so in water, lies the explanation of the therapeutic power, and the freedom from toxicity of Mercodel.

Medical Books Are Splendid Christmas Gifts

GOOD medical books are sensible, practical and highly appreciated Christmas gifts to send to any physician friend or relative, to a medical student, or a faithful nurse. We enjoy assisting in family conspiracies to add up-to-date professional books to the libraries of physician husbands and fathers, many of whom deny themselves really necessary books in order that their families may enjoy every comfort. The books named below are suggestions. We shall gladly send a complete illustrated descriptive catalogue on request and render every possible assistance in the selection of books. Your gifts can be mailed with your card enclosed just before Christmas. Any books found unsuitable may be exchanged before January 10th. Here are our suggestions:

For Any Physician or Surgeon

Stedman's Practical Medical Dictionary. New eighth edition. A splendid big book of 1160 pages, well illustrated, flexibly bound in red, with thumb index —$7.50. *Excellent gift also for a nurse.*
Adams—Works of Hippocrates—$6.00.
Arderne—De Arte Phisicali et de Cirurgia (1412) translated by Sir D'Arcy Power—$4.00.
Comrie—Selected Works of Thomas Sydenham, M. D.—$3.00 (1624).
Hale-White—Selected Passages from Laennec—$3.75.
Singer—Selections from Ambroise Paré—$4.00.
A Superb Gift—Reference Handbook of the Medical Sciences. First and only complete medical encyclopedia in the English language. Eight large volumes, thousands of illustrations. Subscription work. New fourth edition. Price $80.00. Special check-with-order price for Christmas $75.00. Express prepaid. *Ask for Prospectus.*

For the General Practitioner

Bell—Principles of Gynecology, Third edition—$7.50.
Bell—The Sex Complex, Second edition—$6.00.
Bourne—Synopsis of Midwifery—$3.50.
Cabot—Physical Diagnosis, Eighth edition—$5.00.
Campbell—Fundamental Principles in Treatment—$4.00.
Cammidge—Insulin Treatment, Second edition—$2.50.
Clayton—Physio-Therapy in General Practice—$3.50.
Coke—Asthma—$4.00.
Dally—High Blood Pressure—$3.25.
Frumusan—The Cure of Obesity—$2.50.
Herman—Difficult Labor, Sixth edition—$5.00.
Hope—Industrial Hygiene and Medicine—$7.00.
Hornibrook—The Culture of the Abdomen—$2.25.
Hutchison—Food and Dietetics—$5.00.
Hutchison and Sherren—Index of Treatment—$12.00.
Jellett and Madill—Manual of Midwifery—$7.50.
Kerr & Ferguson—Obstetrics and Gynecology—$10.00.
Kingscote—Movement in Organic Disease—$3.50.
Leftwich—Index of Symptoms—$4.50.
Luke—Manual of Physio-Therapeutics—$6.00.
MacKenna—Diseases of the Skin—$6.50.
May—Manual of Diseases of the Eye—$4.00.
Medical Record Visiting List and Physicians' Diary. Size for 60 patients per week—$2.00. Name in gold—25c, with address—50c. *Handsome and practical gift.*
Muthu—Pulmonary Tuberculosis—$4.50.
Russell—Stomach and Abdomen—$4.00.
Savill—System of Clinical Medicine—$9.00.
Short—Index of Prognosis—$12.00.
Walker—Dermatology—$7.00.
Walters—Treatment of Tuberculosis—$4.00.
Wheeler—Handbook of Medicine (Jack)—$4.00.
Wilde—Gout, Rheumatism and Arthritis—$3.50.
Williams—Minor Maladies—$3.25.

For the Surgeon

Adams—Acute Abdominal Diseases—$6.00.
Bertwistle—Radiographs of Bones and Joints—$5.00.
Beesly & Johnston—Surgical Anatomy—$6.50.
Chetwood—Urology—$8.00.
Chiene—Handbook of Surgery—$4.50.
Doyen—Surgical Therapeutics and Operative Technique. Three large volumes, $25.00, 2263 pages, 2975 illustrations.
De Quervain—Clinical Surgical Diagnosis—$14.00.
De Quervain—Goitre—$6.00.
Groves—On Treating Fractures—$8.00.
Jones and Lovett—Orthopedic Surgery—$9.00.
Lejars—Urgent Surgery—$16.00.
McKay—Lawson Tait, His Life and Works—$7.50.
Mummery—Rectum and Colon—$8.00.
Orrin—Emergency Operations—$2.75.
Pickerill—Facial Surgery—$6.50.
Pye—Surgical Handicraft, Eighth edition—$6.50.
Rose and Carless—Manual of Surgery—$11.00.
Schmieden and Turnbull—Operative Surgery—$6.50.

For the Eye, Ear, Nose and Throat Specialist

Axenfeld—Bacteriology of the Eye—$5.00.
Clarke—Refraction of the Eye—$3.50.

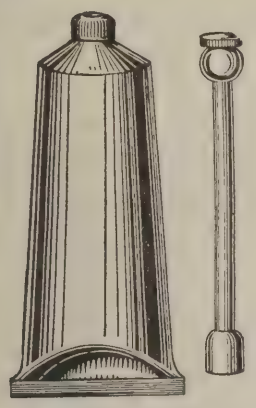
WILLIAM WOOD & COMPANY, *Publishers,* 51 FIFTH AVE. NEW YORK



Full size standard tube contains 4 ounces.

Applicator 4½" long fits on top of tube. Simplifies treatment.

Why More Than 9000 Physicians Are Using Glyeuthymenol

Intra-Vaginal Antiseptic

It is a scientific preparation of eucalyptol, thymol, menthol, sodium benzoate and zinc sulphate on a glycerine base.

It is often effective where the cocoa butter suppository fails, because glycerine unites with secretions. It is a well-known fact that cocoa butter will not do this.

The Glyeuthymenol applicator permits the delivery at every part of the vaginal cavity and the uterine cervix, insuring in this way complete medication.

Thus you have a reliable antiseptic, combined with a glycerine base that insures its compatibility with the physiologic secretions, properly and accurately applied to the surface of the vaginal tract. It is well-nigh impossible to get this result with the suppository or douche.

For these reasons Glyeuthymenol is useful in treating vaginitis. It is also a superior agent for therapeutic cleanliness. It is strictly an ethical preparation and can be obtained only on a physician's prescription.

THE Cabinets illustrated above are typical of Kny-Scheerer Equipment, which is bringing to the Doctor's Office the same economy of space, efficiency and appearance which he has formerly known only at Hospitals. Long experience in the requirements of the medical profession has been applied to the creation of these Cabinets to make them practical, to last indefinitely and to increase the value of the Doctor's time.

Steel construction, white enameled with metal fittings, removable and portable shelves of heavy plate glass, accurately fitting drawers and doors which do not stick—these points make Kny-Scheerer Cabinets sensible business investments as well as essential professional aids.

Genuine Kny-Scheerer Products, which can be identified by our Aesculapius Trademark, are procurable from all representative surgical instrument distributors. If you are unable to secure Instruments, Furniture and Sterilizers of our manufacture from your dealer, we will furnish you with the names of the distributors in your vicinity where products of our manufacture are available. Demand Kny-Scheerer Trademarked Products—Take no substitutes.

HORMONE FEEDING
AND
NATURAL ORGANOTHERAPY

Endocrinologists are agreed that the Natural Organotherapy of the Animal Economy employs and is dependent upon an ample supply of all the Hormones carried in solution in the circulation. The solution is a normal pluriglandular solution and the Hormones are freed from their native protein cells.

A vigorous vitality requires an ample supply of Hormones. The normal supply is limited to the capacity of the endocrine glands. Inordinate demands in excess of the maximum output of the glands, create a deficiency —in which event the most insistent requirements seem to be filled to the detriment of the rest.

Thus in physiological crises normal physical and intellectual activities are subordinated. Conversely, excessive physical or intellectual demands react upon and devitalize the subconscious physiological metabolism.

Accurate analysis of all the endocrine irregularities underlying such conditions is impossible. A general Hormone deficiency is the rule—General Hormone feeding or restoration by the use of *pure liquid Hormones* is, therefore, indicated and in practice has been found to give satisfactory results. *It does not preclude, but will supplement and reinforce specific endocrine treatment in proper cases.* Feeding all the Hormones reinforces a natural condition to which the system is accustomed and accommodated. COLWELLS HORMONES *is unique in its usefulness for this purpose.*

COLWELLS HORMONES contains the essential Hormones wholly free from all proteins or toxins, in a very palatable vehicle. It is non-alcoholic. The solution is a mild one, and the dosage can be arranged readily to meet the requirements of each specific case. It can be varied as to quantity and frequency until Hormone deficiencies are overcome and the emergency requirements complied with.

A free sample, 2 oz. bottle, will be furnished upon application.
Correspondence solicited.

Many Doctors

Are telling patients hot breakfasts can now be prepared in 3 to 5 minutes

If you subscribe to the "hot oats and milk" breakfasts now so widely advocated, we believe you will be glad to know of this new Quaker Oats—Quick Quaker.

We perfected this new Quaker Oats for busy wives and mothers, who, because of limited time, were serving oats too seldom. They cook thoroughly in 3 to 5 minutes. That's as quick as plain toast.

Quick Quaker Oats are the same as regular Quaker Oats. They are rolled thinner and partly cooked. They cook faster; that is the only difference. All that rich Quaker flavor is retained. All the high quality of oats and milling that make Quaker the top brand of the world.

May we suggest that where oats breakfasts are indicated, you will mention this quick cooking feature to your patients.

The Management of an Infant's Diet

Malnutrition, Marasmus, Infantile Atrophy, Athrepsia

Mellin's Food	**8 level tablespoonfuls**
Skimmed Milk (1% fat)	**9 fluidounces**
Water	**15 fluidounces**

This mixture contains 56.61 grams of carbohydrates, thus supplying material that is utilized rapidly for heat and energy. The predominating carbohydrate is MALTOSE, which has the highest point of assimilation of any of the sugars, is immediately available as fuel and may be safely given in comparatively large amounts. The daily intake of protein from the employment of this formula is 15.54 grams, an amount calculated to be sufficient to replace depleted tissues and to provide for new growth. There is present in the mixture 4.32 grams of salts for replenishing inorganic elements.

The suggested modification furnishes nutrition in keeping with the character and amount of food elements best adapted to the particular demands of infants in an extreme state of emaciation and serves well as a starting point in attempting to meet the nutritive requirements of these undernourished babies.

Mellin's Food Co., 177 State Street Boston, Mass.

Pamphlet on Application

WINTHROP CHEMICAL COMPANY, Inc., 117 Hudson St., New York, N. Y.

"For those who suffer from various foot troubles,"

an intelligent and observing shoe salesman was recently overheard to say, "the routine wearing of

O'Sullivan's Heels

is considered by most doctors a very desirable detail."

"And," he continued, "I know this is so because of the increasing number of people who come here to purchase shoes, and inform us their doctors have told them to be sure to have O'Sullivan's Heels attached --- and no others.

"It is easy to understand this preference, for the greater resiliency of O'Sullivan's Heels not only exercises and strengthens weakened foot muscles, but by preventing shock relieves muscular tension with its resulting pain and ache.

"Yes, sir, medical men today are keenly alive to the hygienic value of O'Sullivan's Heels."

O'Sullivan Rubber Co., Inc. New York City

COMBINES the delightful qualities of effervescence with the well-known digestive properties of Peptenzyme.

The powerful and effective action of Peptenzyme, supplemented with the tonic and refreshing effects of effervescence, thus insures both

PERMANENT BENEFIT AND PROMPT RELIEF

in gastralgia, nervous and fermentative dyspepsia, flatulence, atonic indigestion, and to relieve the gaseous fermentation that usually causes so much discomfort in digestive disorders.

It is palatable to the nth degree and gives the physician a cooling and refreshing beverage, free from any hint of medicine, yet pregnant with therapeutic value.

Converts the Distresses of Indigestion into a Smile

SOMETHING NEW

PEPTENZYME EFFERVESCENT GRANULES

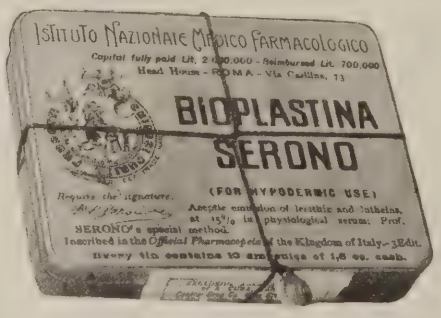
JERSEY CITY, N.J.

In Tissue Exhaustion



A product of the Pharmaceutical Laboratory, Istituto Nazionale Medico Farmacologico, Rome, Italy.

the essential elements must be replaced and the processes of metabolism stimulated.

In the emulsion of lecithin and lutheins as represented by

BIOPLASTINA SERONO

will be found a rational agent for the purpose.

The bioplastic function of BIOPLASTINA SERONO is shown by its power to increase cellular activity and to stabilize metabolism.

BIOPLASTINA SERONO is the essential substance of the cellular nucleins, and introduces into the system lecithin and lutheins, the active and phosphoric substances of embryon. Under its use follows an increase in appetite, red cells, weight and muscular strength.

As an adjunct to mercury in the treatment of syphilis, especially in the presence of cachexia, the use of BIOPLASTINA SERONO is definitely indicated. Also in anemia, rachitis, nervous exhaustion, premature senility and similar states, it will be found of more than ordinary worth.

Sample and literature sent on request.

The ADRENALIN *Group*

WHEN you specify "Adrenalin, P. D. & Co." in your prescriptions or orders, you give your patient the benefit of more than twenty years of manufacturing experience with the pressor principle of the suprarenal gland, discovered by Takamine in 1900 and placed upon the market by Parke, Davis & Company in 1901.

Adrenalin is a life-saver in more senses than one. Its effect upon the arterial system and the heart is phenomenally swift and potent; while for antiphlogistic effect on the inflamed mucosa in nasal, laryngeal, rectal and genito-urinary conditions, it is unexcelled. Invaluable in shock, collapse, serum rash, and to control operative hemorrhage. The one reliable symptomatic remedy for asthma.

Among our Adrenalin preparations the following deserve to be constantly kept in mind:

ADRENALIN INHALANT (1:1000)

Indicated in acute, subacute or chronic rhinitis, pharyngitis, tonsillitis, laryngitis; in scarlatinal angina, and in hay fever. A pronounced astringent.

ADRENALIN OINTMENT (1:1000)

Used for the same purposes as the Inhalant, and in urethritis for its astringent effect. A serviceable lubricant for urethral instruments.

ADRENALIN SUPPOSITORIES (1:1000)

ADRENALIN AND CHLORETONE SUPPOSITORIES

In hemorrhoids, proctitis, rectal pruritus, or rectal fissure, these suppositories are very serviceable. Cone-shaped; melt at body temperature. Insert one suppository at night and one in the morning.

Write us for our booklet, "Adrenalin in Medicine."

KLIM
POWDERED
WHOLE MILK
MERRELL-SOULE CO.
SYRACUSE N.Y.

Recognizing the importance of scientific control, all contact with the laity is predicated on the policy that KLIM may be used in infant feeding only according to a physician's formula.

KLIM has a high nutritive and assimilative index

THE casein of KLIM, when attacked by digestive juices, coagulates in a flocculent mass rather than in the tough curds characteristic of natural milk.

The butterfat of KLIM retains the globular form of natural milk, but in a much finer division.

The result must be a speedier and more complete metabolism, less inclination to colic, and an absence of the regurgitation which frequently accompanies the feeding of natural milk.

Samples sent promptly upon request

To physicians using their letterheads we shall also send Scientific Literature on all Merrell-Soule laboratory controlled products for infant and invalid feeding.

MERRELL-SOULE CO., SYRACUSE, N. Y.
Also Makers of Merrell-Soule Powdered Protein Milk

Trustworthy!

The extent to which innumerable practitioners of medicine are today employing

Gray's Glycerine Tonic Comp.

(Formula Dr. John P. Gray)

whenever a dependable reconstructive tonic is called for, tells in no uncertain way of its therapeutic utility and gratifying efficiency.

During the thirty-five years this reliable tonic has been at the service of the profession, the quality of its ingredients and the unvarying character of the composite product have been consistently and faithfully maintained.

Thus it is easy to understand why the host of medical men who have learned how reliable it is in its character and results, not only take pains to order the original Gray's Glycerine Tonic Comp. (P. F. Co.), but also to see that their patients get no other!

Such care is well worth while, for it often measures the difference between success and failure.

The Purdue Frederick Co., 135 Christopher St., New York

Valentine's Meat-Juice

Whenever the **Stomach** from any cause **Rejects Food** or **Medicine, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.** In the **Depressing Prostration** following **Influenza,** and in the **General Debility** of **Phthisis, Valentine's Meat-Juice** is recommended by many practitioners throughout the world as invaluable in their treatment.

Influenza *and* Phthisis.

Dr. Boulland, *Paris, France:* "In an attack of La Grippe accompanied by complete lassitude, I used VALENTINE'S MEAT-JUICE. With this preparation I established an excellent appetite and restored my strength very rapidly."

E. H. Walker, *Resident Medical Officer Boro Isolation Hospital and Boro Tuberculosis Sanatorium, Derby, England:* "I have pleasure in stating that I have found VALENTINE'S MEAT-JUICE valuable in the treatment of soldiers discharged from the Army suffering from Pulmonary Tuberculosis."

Physicians are invited to send for brochures containing clinical reports.

DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Amendments to the State Sanitary Code.—At a meeting of the Public Health Council held on October 9, 1924, regulation 53 of Chapter II of the State Sanitary Code was amended to take effect October 15, 1924, and to read as follows:

Regulation 53. Public funerals forbidden in certain cases. A public or a church funeral shall not be held of any person who has died of a communicable disease excepting anthrax, botulism, glanders, ophthalmia neonatorum (suppurative conjunctivitis of the newborn), paratyphoid fever, pneumonia. puerperal septicemia, rabies, tetanus, tuberculosis and typhoid fever, unless the consent of the local health officer has first been obtained.

Race Integrity Law.—Eugenical marriage regulations, as one phase of them is developed in the Virginia racial integrity law, were discussed before the Detroit meeting of the American Public Health Association by Dr. W. A. Plecker, State Registrar of Vital Statistics of Virginia. Dr. Plecker pointed out that the American race problem started within twelve years after the first English settlement in America, when negro slaves were introduced. The Virginia law prohibiting intermarriage of white and colored persons was placed on the books, he declared, because it had been shown that where different races came into contact there was always a tendency for them to intermix; and it was believed that our civilization depended upon keeping the purity of the white race intact. He urged the nineteen states that now permit legal marriage of whites with colored or mixed bloods, to adopt laws forbidding it.

The Public Health Service Studies Influenza and the Common Cold.—The common cold is the most prevalent illness in the United States and apparently many such colds are quite contagious, says the Surgeon General of the Public Health Service, few people failing to experience at least one attack during a twelve month period, while many persons have three or more attacks during that time. These facts are borne out by data recently secured by officers of the Public Health Service in an investigation of influenza and the minor respiratory diseases which they are conducting at the present time.

That large numbers of persons have colds each year is common knowledge but just what percentage of people, as a rule, have attacks and the average number of colds a year for each person have not been known, as the disease is not required to be reported by law, and, therefore, the morbidity records do not show that information.

In a preliminary report of the investigation that is now in progress, the Public Health Service shows that among a fairly representative group of persons only ten per cent. had no colds, while ninety per cent. had one or more colds during a five and a half month period; the rate for the group as a whole for that period being 1.9 cold for each person, or an annual rate of 3.7 cold a person should the same rate obtain throughout the year.

The cold was found to be the predominant form of respiratory attack. The relative frequency of symptoms was shown to be very much the same for all localities, and the epidemic outbreaks occurred apparently at about the same time of year in each locality. An outbreak of colds usually occurred in all localities in October, followed by a decline until the latter part of December, at which time another outbreak occurred.

It is now believed that there may be a closer correlation between the common cold and influenza than was formerly thought to exist. There seem to be cases of common cold and ordinary influenza which are almost indistinguishable clinically, and the bacteriological findings in the nose and throat of influenza sufferers and persons having a common cold are as far as the evidence goes practically the same. As a matter of fact, even in health the bacteria found in the minor respiratory diseases are nearly always present, which at once suggests that good resistance provided by physical fitness is an important line of defense, since a lowered vitality and lowered resistance favor infection. We can not depend upon physical fitness alone, however, as robust persons may apparently contract a cold from an infected person.

The investigation now being undertaken by the Public Health Service is the first nationwide study of influenza and colds ever made, and the final results are awaited with much interest, in the hope that further light will be shed on these affections which yearly cause much suffering, inconvenience, economic loss, and, in the case of influenza, even deaths, and which, as far as their cause and prevention are concerned, are up to the present time comparatively little understood.

Medical Fellowships Awarded.—Fourteen graduates in science have been awarded medical research fellowships by the National Research Council, for special training in teaching and important investigational work in the various branches of medicine and the medical sciences. The newly appointed fellows are in addition to the twenty-nine already at work under grants from the Medical Fellowship Board of the National Research Council. The actual research is conducted at various institutions throughout the world and about a fifth of the fellows study abroad. Whether a fellow is married or single the time of appointment determines in part the compensation that is granted him from the fellowship fund made available to the National Research Council by the Rockefeller Foundation and the General Education Board. An unmarried fellow receives $1,800 a year, while a married man receives $500 more. Many of the fellows before the expiration of their fellowships have been invited to fill desirable teaching and research positions.

Those who have just been appointed and the institutions where they will work are: Dr. Emily B. Carrier, Harvard University; Dr. Benjamin Freeman, University of Pennsylvania; Dr. M. S. Hollenberg, Johns Hopkins University; A. E. Mirsky, University of Cambridge, England; Dr. H. L. Pelham, Columbia University; Dr. Bernhard Steinberg, Western Reserve University; Dr. F. W. Stewart, Boston City Hospital; Dr. G. J. Strean, University of Iowa; Dr. C. H. Theines, Stanford University; Dr. J. L. Goforth, Dr. Erida L. Leuschner, and Dr. H. B. Van Dyke, place not yet determined; Dr. Frederick P. Gay, of Columbia University, is chairman of the Medical Fellowship Board.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

An invaluable aid for strict oral disinfection

THE oral cavity, being an ideal habitat for pathogenic micro-organisms, naturally forms an avenue of invasion for infection.

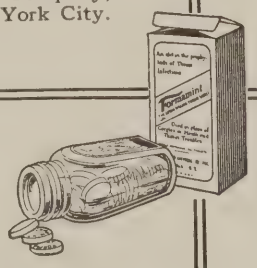
As a remarkably effective means of combating these micro-organisms, Formamint fulfills a definite and much needed function.

Being in tablet form, Formamint can be held in the mouth where it will dissolve slowly in the saliva, and give off nascent Formaldehyde which penetrates to the innermost recesses and folds of the mucous membrane. This germicidal action can be repeated at frequent enough intervals to make the treatment continuous.

Formamint tablets are harmless and pleasant to the taste. Their convenience of administration renders them a welcome and dependable agent for mouth and throat disinfection and prophylaxis.

We shall be pleased to place at the disposal of any member of the profession enough samples for a thorough test. Address The Bauer Chemical Company, 113 West 18th Street, New York City.

Formamint
GERM-KILLING THROAT TABLETS



Typhoid Carriers.—On October 1, 1924, the total number of typhoid carriers listed in New York State, exclusive of New York City and State hospitals, was ninety-six. Of this number twelve have been discovered and added to the list since January 1st. The histories of these carriers indicate that in several instances they had probably been the source of one or more cases in previous years.

Points in the histories of the twelve carriers discovered in the first nine months of the present year are as follows:

1. A housewife, living on a dairy farm, believed to have been the source of typhoid infection of two cases in 1922 and of five cases in 1923. Carrier had typhoid in 1878.
2. A dairy farmer, to whom typhoid in one and possibly two of his sons is ascribed. Had typhoid in 1917 or 1918.
3. A house mother in a children's home; an outbreak of twenty-three cases attributed to her as a source of infection. No history of typhoid.
4. A laborer on a dairy farm; said to have been the source of two cases on the farm where he was employed at the time of discovery and of two cases in a family which obtained milk from this farm. Had typhoid about 1900.
5. Source of typhoid infection in husband. Had typhoid in 1923.
6. After recovery from typhoid in 1923 became a chronic carrier.
7. A grandmother who infected a grandson after taking up residence in the home of the child's parents. Also possibly source of disease in visitor to household. Carrier had typhoid summer of 1923.
8. A nurse in a small hospital developed typhoid fever and an examination of the personnel showed that a temporary cook was a fecal carrier although she denied a history of typhoid fever. Our first information was to the effect that this woman, sixty-eight years of age, had been associated with but one previous case of typhoid although she had been employed as cook and housekeeper for a number of years. As this seemed too remarkable to credit without confirmation, further inquiry was made. This brought out that her husband had typhoid in 1901, a daughter-in-law and a neighbor in 1904, a grandson in 1907, a brother in 1920, and a woman with whom she lived in 1922. This carrier's employment in the hospital lasted only a week and she had been gone from the hospital nearly a month at the time specimens were obtained.
9. A child ten years old who infected his younger brother in May, 1924. Had typhoid in September, 1923.
10. Source of typhoid in a niece about six months after the carrier had become a member of the household. Had typhoid in 1904.
11. Source of typhoid infection of an aunt, father, a brother and a hired man at home and later was employed on a farm where her fiance subsequently came down with typhoid. Had typhoid in 1918. The aunt noted above was already known as a carrier, having been discovered in 1920 following typhoid in her nephew.
12. A meat dealer who had typhoid in 1918. Discovered incidentally to a search for the cause of sporadic cases occurring over a series of years in a rural community.

In addition to the carriers proved to be such by bacteriological examination, four other persons have been listed as suspected carriers. One of these was employed as the cook in a family on a farm which was visited by three persons who subsequently came down with typhoid fever in a nearby city. This carrier was lost track of before specimens could be obtained. Still another woman who gave a history of having had typhoid in the past is suspected of being the probable source of typhoid infection of her husband and grandchild. Specimens are to be submitted. A man who is known to have had typhoid fever some years ago is suspected as the probable source of a number of cases in a village in Central New York because of his social relations to them. Specimens are to be submitted. Another suspect is a man who was employed in the handling of food for public consumption. One fecal specimen from him has been found positive; other specimens are to be submitted for confirmation.

There were ninety carriers listed with the Division of Communicable Diseases on the first of January. In addition to the twelve newly discovered carriers added to the list, two carrers who had been out of the state returned. Two other carriers moved out of the state, one previously listed as a known carrier was transferred to the suspected list, four died, and one was successfully operated upon for removal of the gallbladder. Eight of the twelve carriers have been discovered as the result of efforts by local health officers, two by attending physicians and two by representatives of the state health department. The large proportion discovered by local health officers is a tribute to their interest and their abilities as epidemiologists.

Students' Health Closely Watched at Lehigh University.—Scenes reminiscent of the army cantonments of war times were enacted in the newly established Students' Health Department at Lehigh University during the past week. Each of the 1300 undergraduates was required to undergo a physical examination at the time of his registration. While a physical examination has long been required of every entering student at Lehigh, no such rigid tests have ever before been attempted. In fact, it is probable that no other institution has attempted to supervise the physical condition of its undergraduates as thoroughly as the Lehigh authorities have done this year.

Under the direction of Dr. R. C. Bull the examination was so efficiently organized that 610 men were thoroughly examined in three days. Each man was examined by ten specialists, passing from one to another in rapid succession. The first examination was for general appearance, height, weight and chest measurement. The applicant then passed to a test of his color vision. From here he was examined by the representative of the physical education department who made note of his natural posture, the condition of his joints and tests of his principal muscles. From these latter data corrective exercises will be prescribed for each individual. The fourth stop for the candidate was a dentist's chair where his teeth were thoroughly inspected by one of the six dentists of Bethlehem who volunteered their services for this work. Passing from the dentist, each man had a test made of his vision and hearing; then his nose and throat were examined by specialists in this field after which a surgical examination was made followed by inspection of his nervous system, chest and skin. Of the 610 men examined during the first three days, 383 were vaccinated for smallpox. The final test was the obtaining of a laboratory specimen after which the man was given his certificate.

The Department of Biology at the University cooperated with the Students' Health Service in the examination and all the vaccination was done under the direction of Professor Stanley Thomas of that department. The technic used was that employed by the U. S. Public Health Service at the New York Quarantine Station, which indicates whether the patient is immune to the disease.

Health Problems of the Small City.—Public health in cities of twenty to thirty thousand population is far less efficiently safeguarded than it is in larger places, according to Prof. Ira V. Hiscock, of the Yale School of Medicine, who addressed the American Public Health Association, at Detroit. Prof. Hiscock has made a detailed study of smaller cities in Connecticut. In communities of this size, he pointed out, there is a lack of full time employees, trained in modern health practice. Too frequently the combination of job of health officer and school physician becomes a political "plum." The appropriations for official health work in over nine tenths of these towns are inadequate for the development of a complete health progress. Volunteer work by partly qualified nurses, cooperation by parents in health undertakings fostered through the public schools, and a gradual awakening of public feeling, promise possible improvement in the future.

Iodine Requirements for Water.—The needs of inland populations for iodine in diet or water supply, to prevent the incidence of goitre, were the subject of a report to the American Public Health Association by a committee on nutritional problems, under the chairmanship of Dr. Henry C. Sherman of Columbia University. Dr. Sherman pointed out that in regions near the seashore the iodine necessary for good health is borne inland to considerable distances as spray on the wind; but in regions remote from the sea or cut off by mountains, there arises a lack of iodine, and a consequent increase in the occurrence of goitre. Little iodine is necessary to prevent goitre —only about one part in three million parts of the body weight. This may be supplied, in inland places, by adding slight amounts to city water, by the addition of iodine salts to common salt or in other ways introducing it into food, or by using in the diet small quantities of sea plants which have been found to be rich in iodine.

Swedish Physician Says Tuberculosis Cures Diabetes.—The curious fact that diabetes can sometimes be cured by tuberculosis has led a prominent Swedish specialist, Dr. Erik Lundberg, to researches and discoveries which promise to have important effect on the future treatment of both diseases. This is of special interest in connection with the widely heralded use of insulin in the relief of diabetes. Proceeding on the theory that in the case of consumptive patients insulin, or something similar, is secreted outside of the pancreatic gland, Dr. Lundberg experimented with mice which he infected with tuberculosis and then dosed with insulin. He succeeded in producing insulin poisoning which led to instant death, except where he made injections of grape sugar along with the insulin. He found that the injection of about half a cubic centimetre of a solution of ten per cent. grape sugar resulted in immediate recovery from the insulin poisoning. From these experiments Dr. Lundberg has concluded that insulin is secreted by the tuberculous granular tissue, and that this substance is everywhere present in the human organism in every small quantities, where the secretion is greatly stimulated in some way under the influence of tuberculosis bacilli or their toxins.

AN APPEAL

By the Physicians' Committee for the Aid of the Refugee Physicians in Europe

A. J. RONGY, M.D., Chairman 590 West End Avenue	I. D. HELD, M.D., Treas. 940 Park Avenue	J. SAPHIR, M.D., Sec'y. 345 W. 88th Street

There are in Europe about 400 refugee physicians. They have no means of gaining a livelihood. They are suffering extreme privations. Some do menial work—most of them cannot get even that.

This committee is endeavoring to raise a fund to help these unfortunate physicians and their families.

Their position is very critical; help must be given them immediately.

We appeal to you in behalf of our colleagues who are in distress.

Won't you help them and send your contribution today?

Please send check to Dr. I. W. Held, Treasurer, 940 Park Avenue.

Cordially yours,

A. J. RONGY, M.D., *Chairman.*

For many years Rheumatism has been a bugbear of medicine. . . . There is no doubt in my mind that in time the intravenous route will prove our choice of therapeutic armamentarium in alleviating this condition.—T. J. Riordan in *Clinical Medicine.*

ROBES'
INTRAVENOUS
PRODUCTS, INC.
Department 20
World's Tower Bldg.,
110-112 West 40th St.,
New York, N. Y.

Dr. Riordan's prediction is daily being fulfilled, for an ever-increasing number of progressive practitioners are becoming clinically convinced of these three facts:

(1) The logical and rational method of attacking Rheumatism in all its forms is by the intravenous route;

(2) Therapeutically, the most effective injection has been found to be a combination of certain chemical ingredients dissolved in physiological salt solution;

(3) This remedy is known as Robes' Anti-Rheumatic Injection.

BOWEL INACTIVITY

calls for efforts that not only will empty but restore as promptly and satisfactorily as possible, the physiologic action and tone of the intestinal tract. To accomplish this

PRUNOIDS

has no superior. Absolutely free from irritating effect, this ideal laxative never gives rise to griping or extreme peristalsis, but through its stimulation of natural processes, produces as near to normal—or physiologic—evacuations, as may be possible.

BALTIMORE MD.

You Can Relieve Your Patients' Pain

With promptness and efficiency, and *Without* the gastric irritation of the salicylic acid preparations, the habit forming tendencies of the opiates, or the special blanks and records required in using narcotic products, by the use of PHENALGIN.

A physician needs only to give PHENALGIN a reasonable trial in a few painful affections to note its advantages over the salicylates, opiates and pain relieving remedies in general.

PHENALGIN
Prompt -- Effective -- Safe

REGULIN

Presents a new principle in the conquest of chronic constipation — that of treating the bowel contents rather than the bowels themselves. Corrects the physical condition of the intestinal mass — restores its normal bulk and softness—and the bowels resume their natural functioning. REGULIN is a true bowel corrective.

THE JEFFERSON MEDICAL COLLEGE

OF PHILADELPHIA

ONE HUNDREDTH ANNUAL SESSION BEGINS SEPTEMBER 23, 1924, AND ENDS JUNE 5, 1925

FOUNDED 1825. A CHARTERED UNIVERSITY SINCE 1838. One of the oldest and most successful medical schools in America. Graduates number 14,338, about 6,000 of whom are active in medical work in every State, and many foreign countries.

FACILITIES: Well equipped laboratories; separate Anatomical Institute; teaching museums; free libraries; unusual and superior clinical opportunities in the Jefferson Hospital, Jefferson Maternity, and Department for Diseases of the Chest.

A sixteen-story addition to the Jefferson Hospital costing more than Two Million Dollars to build and equip, containing the New Clinical Amphitheatre, the Maternity Department and the new Clinical Laboratories will be completed and ready for occupancy prior to the opening of the session.

These buildings are all owned and controlled by the College. Instruction privileges in six other Hospitals.

FACULTY: Eminent medical men of national reputation and unusual teaching ability.

ADMISSION: Not less than two College years leading to a degree in science or art, including specified science and language courses. Preference is given to those who have completed additional work.

APPLICATIONS should be made early.

ABUNDANT OPPORTUNITIES for graduates to enter hospital service and other medical fields.

ROSS V. PATTERSON, M. D., Dean

JEWEL ELECTRIC FOUNTAINS

We make several styles of portable illuminated electric fountains for the home and office. The clear sparkling water falling on the artistic illuminated shade makes a beautiful decoration for sun-parlors or living rooms. They are portable and can be moved to any room as they do not require any water connection. The top container can be lifted off this two piece reed stand for table use. The beautiful art glass splash ring reflects the light. Our Jewel Fountain is an excellent humidifier and it cools the atmosphere in Summer. Its artistic beauty will make it a joy forever in your home.

Physicians' offices are just the place for our fountains as they are an ideal decoration. Send ten cents for our illustrated catalog.

Mile-stones of Accomplishment

Over ten years ago a certain idealist named Harrower set out "to develop information pertaining to the internal secretions in general practice." His aim was the establishment of a non-commercial, philanthropic institution devoted to the study and development of practical knowledge in endocrinology.

Subjoined is a record of the mile-stones of accomplishment which led to the realization of this ideal:

1914—Publication of "Practical Hormone Therapy."
1916—Founding of the Association for the Study of Internal Secretions.
1917—Establishment of the first journal in this special field—*"Endocrinology."*
1918—Founding of The Harrower Laboratory.
1919—Erection of first building.
1921—Erection of administration building.
Inauguration of "The Harrower Foundation," a charitable organization incorporated under the laws of the State of California.
1923—Establishment of THE ENDOCRINE SURVEY, as a convenient, inexpensive survey of the interesting and the practical in endocrinology.
1924—(November)—Inauguration of THE HARROWER FOUNDATION CLINIC.

The new Clinic, which is supported by The Harrower Foundation, makes possible, under ideal conditions, the furtherance of research work in endocrine problems of a clinical and laboratory nature.

In this Clinic are found the best facilities for the diagnosis and treatment of endocrine disorders, and physicians may avail themselves of these unexcelled advantages for the complete investigation of their problem cases, for laboratory research in connection with their own diagnostic efforts and for postgraduate study. Lectures and clinical demonstrations, which are open without charge to any medical practitioner, are held from time to time.
